ABSTRACT

Oxidative stress-induced damage to the retinal pigment epithelium (RPE) is considered to be a key factor in age-related macular degeneration (AMD) pathology. RPE cells are constantly exposed to oxidative stress that may lead to the accumulation of damaged cellular proteins, lipids, nucleic acids, and cellular organelles, including mitochondria. The ubiquitin-proteasome and the lysosomal'autophagy pathways are the two major proteolytic systems to remove damaged proteins and organelles. There is increasing evidence that proteostasis is disturbed in RPE as evidenced by lysosomal lipofuscin and extracellular drusen accumulation in AMD. Nuclear factor-erythroid 2-related factor-2 (NFE2L2) and peroxisome proliferator-activated receptor gamma coactivator-1 alpha (PGC-1 α) are master transcription factors in the regulation of antioxidant enzymes, clearance systems, and biogenesis of mitochondria. The precise cause of RPE degeneration and the onset and progression of AMD are not fully understood. However, mitochondria dysfunction, increased reactive oxygen species (ROS) production, and mitochondrial DNA (mtDNA) damage are observed together with increased protein aggregation and inflammation in AMD. In contrast, functional mitochondria prevent RPE cells damage and suppress inflammation. Here, we will discuss the role of mitochondria in RPE degeneration and AMD pathology focused on mtDNA damage and repair, autophagy/mitophagy signaling, and regulation of inflammation. Mitochondria are putative therapeutic targets to prevent or treat AMD.

1. Introduction to RPE degeneration and development of AMD

AMD is associated with several environmental and genetic risk factors that are linked to increased oxidative stress (Fig. 1; Handa, 2012; Jarrett and Boulton, 2012; Fritsche et al., 2013; Kaarniranta et al., 2018a,b; Wang et al., 2018). Per definition, age is the main risk factor for AMD. The accumulation of oxidized proteins, lipids, and DNA in aged tissues provides evidence for an overall increase in oxidative stress with aging (Ames and Shigenaga, 1992; Moldogazieva et al., 2019). The main genetic factors in AMD are mutations in the genes of

the complement factors H, B and I (CFH, CFB, CFI), complement components 3 and 2 (C3, C2), as well as Age-Related Maculopathy Susceptibility 2/High-Temperature Requirement protein A1 (ARMS2/HTRA1) gene regions (Fritsche et al., 2013). Evidence linking genetic backgrounds with elevated oxidative stress included the significantly higher RPE mtDNA damage reported in donors harboring the CFH high risk alleles (Ferrington et al., 2016a). Dysfunctional CFH reduces antioxidant capacity and energy metabolism of human RPE cells (Armento et al., 2020). Additionally, the presence of the ARMS2/HTRA1 risk alleles in induced pluripotent stem-RPE cells (iPSC-RPE) resulted in

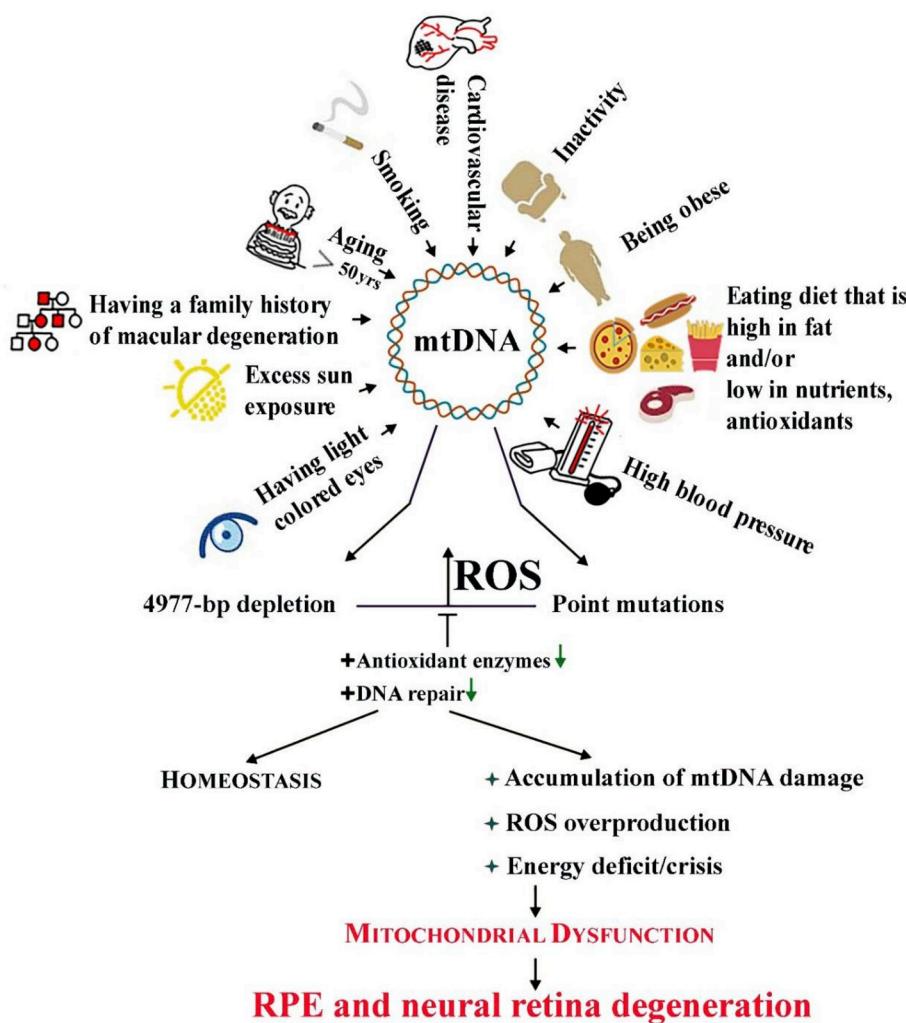

Fig. 1. Mitochondrial DNA (mtDNA) in the neural retina and retinal pigment epithelial (RPE) cells can be damaged by many endogenous and exogenous factors, including some risk factors of age-related macular degeneration (AMD). Aging, the primary AMD risk factor, is also associated with induction of mtDNA damage. It is likely that mtDNA damage affects genes encoding the mitochondrial electron transport chain resulting in reactive oxygen species (ROS) overproduction, leading to more damage to mtDNA. These changes can be counterbalanced by efficient (+) antioxidant enzymes or DNA repair, but when these systems fail, accumulated damage to mtDNA can result in mitochondrial dysfunctions, energy crisis, cell degeneration and death observed in AMD.

decreased antioxidant defenses, thereby making the RPE more susceptible to oxidative damage (Yang et al., 2014). Smoking, obesity, arteriosclerosis, hypertension, hypercholesterolemia, an unhealthy diet, and excessive light exposure are central environmental or systemic risk factors in AMD (Fig. 1; Blasiak et al., 2019). Each of these environmental risk factors are known to increase oxidative stress and/or inflammation, characteristics that can precipitate retinal pathology (Datta et al., 2017; Rozing et al., 2019).

The devastating effects of AMD are most apparent in the macula, a small, cone-rich area of the retina responsible for high acuity and color vision (Fig. 2A). The macula is under considerable oxidative stress due to its high metabolic rate, high oxygen tension, and the continuous production of reactive oxygen species (ROS) in the area (Stefánsson et al., 2011; Eells, 2019; Stefánsson et al., 2019). In AMD, pathological changes can be observed in the choriocapillaris, Bruch's membrane, RPE, and photoreceptors (Fig. 2B). However, it has been hypothesized that the RPE play a key role in the pathogenesis of AMD due to their central location between Bruch's membrane and photoreceptors where they serve as a conduit for oxygen, nutrients, and waste products between the outer retina and the choriocapillaris (Strauss, 2005; Kaarniranta et al., 2009). In clinical settings, a primary hallmark of AMD is the presence of drusen between the RPE and Bruch's membrane, with RPE degeneration occurring as the disease progresses (Fig. 2A and B). Since one of the main functions of the RPE is to maintain the health of the photoreceptors, RPE degeneration secondarily leads to dysfunction of the photoreceptors and visual disturbances associated with AMD (Fig. 2C).

Oxidative stress and damage have been suggested as key factors for triggering RPE degeneration. Oxidative stress ultimately involves an excess of ROS that are produced mainly in mitochondria (Handa, 2012; Blasiak et al., 2013). ROS oxidize many biological macromolecules, including proteins, lipids, and nucleic acids, and may evoke structural and functional changes in these molecules. In AMD pathology, excessive ROS and oxidized lipoproteins lead to protein misfolding, aggregation, and chronic activation of the innate immunity response (Ferrington et al., 2016b; Kauppinen et al., 2016; Kaarniranta et al., 2019). Various products of lipid peroxidation, such as advanced glycation-end products, carboxyethylpyrrole, malondialdehyde, and 4-hydroxyneonenal, which are indicators of increased oxidative stress, have been detected in macula of AMD patients (Hyttinen et al., 2018). In addition to these products of oxidation, there is an accumulation of autofluorescent lipofuscin, cytoplasmic aggregates, and drusen in AMD that are indicators of disturbed proteostasis, which involves the coordinate regulation of protein synthesis, folding, and degradation. Evidence for defects in protein degradation in the RPE of donors with AMD includes the increased content of both ubiquitin (Ub) and sequestosome-1 (p62/SQSTM1), suggesting failure in the Ub-proteasome and lysosome/autophagy pathways, respectively (Fig. 2D and E). A deficiency in cellular proteostasis has been associated with multiple age-related degenerative disorders and has particularly devastating consequences in post-mitotic or quiescent cells, such as neurons and the RPE (Ferrington et al., 2016b).

Activation of protective pathways and upregulation of endogenous antioxidants are cellular responses against excessive oxidative stress.

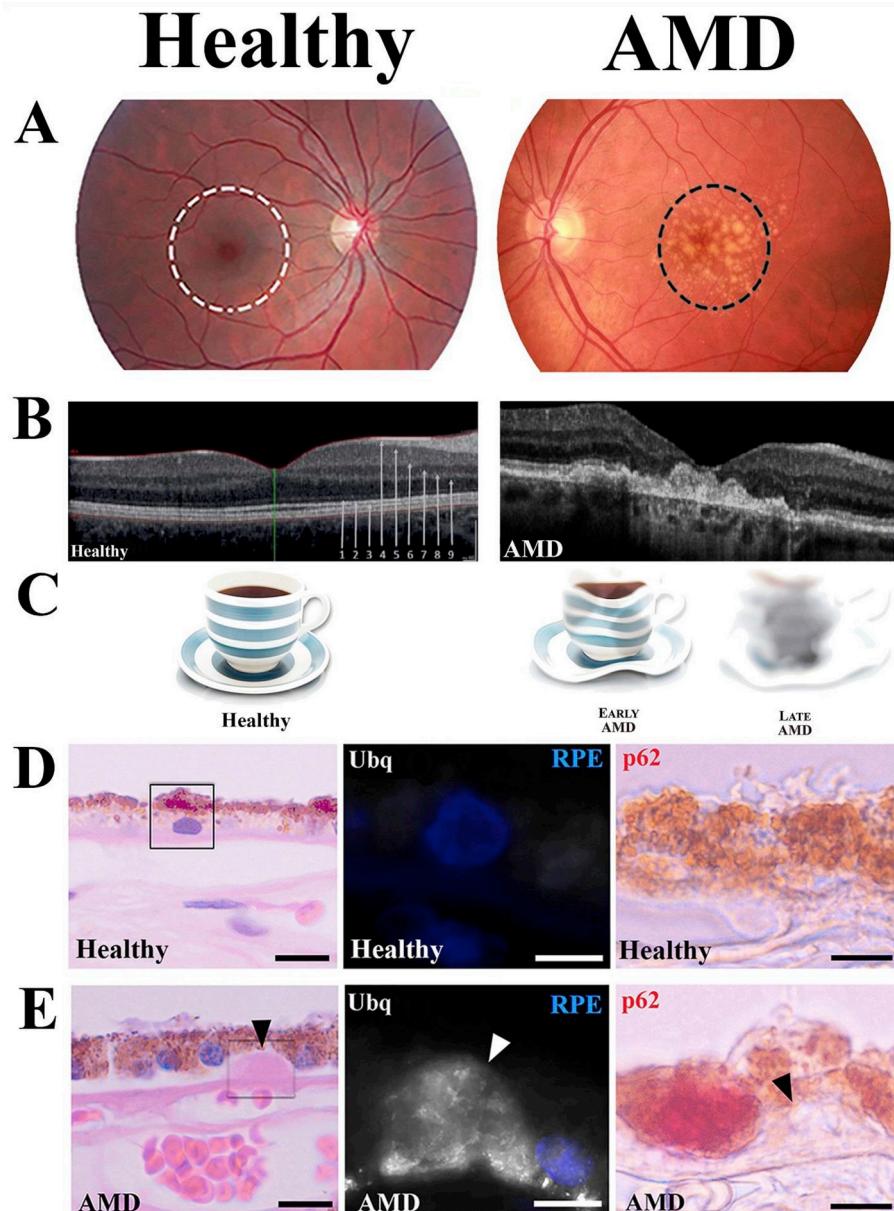

Fig. 2. Dry age-related macular degeneration: symptoms and signs. (A) Color fundus photograph from normal and dry AMD patient maculas. The central macula controls sharp and color vision (white ring). Drusen are the clinical hallmarks of AMD (dark ring). (B) Optical coherent tomography (OCT) from the healthy and AMD retinas. Arrows indicate different layers of the retina: 1) external limiting membrane, 2) ellipsoid layer, 3) RPE layer, 4) retinal nerve fiber layer (RNFL), 5) ganglion cell layer, 6) inner plexiform layer, 7) inner nuclear layer, 8) outer plexiform layer 9) outer nuclear layer. (C) Representative vision disturbances during the progression of AMD. (D) Light microscopic image of hematoxylin-eosin (HE) stained human retina from (D, left panel) healthy and (E, left panel) AMD donors. High power confocal images indicate extracellular ubiquitin (Ubq, middle panels) and intracellular p62 (right panels) stainings. Arrowheads show drusen accumulation. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

Antioxidative defense mechanisms can also improve autophagy, thereby increasing survival of RPE cells (Kaarniranta et al., 2017, 2018a). Among the protective pathways are the NFE2L2 and PGC-1 α , which upregulate expression of antioxidants that protect against ROS-induced mitochondrial damage and cell death (Strom et al., 2016 <https://onlinelibrary.wiley.com/doi/full/10.1111/ace.12650>). PGC-1 α also regulates the expression of many genes important for energy production and mitochondrial biogenesis (Kaarniranta et al., 2018a, b). Understanding how these pathways are involved in AMD and how they could be manipulated to protect RPE *in vivo* is critical to study.

We summarize data supporting the hypothesis that mitochondrial dysfunction in the RPE is a key event in AMD pathology. A significant increase in mtDNA damage is associated with normal aging, but it is more extensive with AMD. There is evidence that mitochondrial DNA damage repair and haplogroups are involved in the pathology of AMD. NFE2L2 and PGC-1 α have a key role in mitochondrial quality control and in the regulation of protein aggregation and inflammation in AMD. We also discuss mitochondria as a putative therapy target to prevent or treat AMD.

2. RPE mitochondria damage and dysfunction during normal aging

Mitochondria are crucial organelles that produce adenosine triphosphate (ATP) via oxidative phosphorylation, which involves the transfer of electrons between multi-subunit complexes (I to IV) of the Electron Transport Chain (ETC) coupled with the reduction of molecular oxygen. Under normal circumstances, ~2–5% of the oxygen is incompletely reduced, leading to elevated ROS and superoxide production (Chen et al., 2003). Even the act of phagocytosis, one of the daily functions of the RPE, predisposes these cells to altered mitochondrial redox states and increased mtDNA damage (Jin et al., 2001; Liang and Godley, 2003). Several studies show a dual role for ROS in cell physiology: (i) Moderate amounts of ROS are essential for the maintenance of beneficial cellular processes, such as production of cellular energy and the regulation of mitochondria protective signaling pathways. Upregulation of these positive effect are capable of increasing lifespan in lower organisms (Giorgi et al., 2018), (ii) In contrast, excess ROS are pathogenic and may evoke accelerated cell degeneration or even cell death.

Mitochondrial ROS and oxidative damage are significantly increased with aging and aging-related diseases. For example, opening of the mitochondrial permeability transition pore, which is triggered by ROS and mitochondrial calcium overload, leads to apoptosis (Rottenberg and Hoek, 2017). The increased ROS levels promote oxidative damage to mitochondrial DNA, lipids, and proteins (Jarrett et al., 2008). During normal aging, a disruption of mitochondrial structure and an accumulation of mtDNA mutations have also been reported (Blasiak et al., 2013). These results are in line with earlier studies of Wang et al. who showed an accumulation of mtDNA damage with age in RPE and choroid of mice and rats (Wang et al., 2008). This effect was likely the result of the decrease in DNA repair capacity with age, which was supported by a decreased expression of genes encoding 8-oxoguanine-DNA glycosylase 1 (OGG1), MutY DNA glycosylase, and thymine DNA glycosylase – enzymes critical for repairing oxidative damage to DNA. However, DNA repair is not the only way the cell may act against mtDNA damage as it can be prevented by antioxidant enzymes and small molecular weight antioxidants (Fig. 1; Tokarz et al., 2013). Furthermore, it seems that these studies suffer from the lack of evaluation of the DNA repair capacity in cells challenged by an endogenous DNA-damaging factor, which is important in the context of AMD pathogenesis, as aging is its main but not the only risk factor. In their subsequent work, Wang et al. showed that photoreceptors and retinal ganglion cells in rodents also displayed increased levels of mtDNA damage and again this effect was attributed to decreased DNA repair capacity (Wang et al., 2010).

Damage to the mitochondrial genome also involves a 4977 base pair deletion, known as the “Common Deletion”, which occurs with high frequency in patients with mitochondrial diseases, and also in aged post-mitotic and quiescent cells including the RPE and neural retina (Fig. 1; Barreau et al., 1996; Karunadharma et al., 2010; Nie et al., 2016; Huang et al., 2018). These results were confirmed in subsequent research, showing a biphasic increase in the ratio of this mutation in the retina. A slow increase occurred in donors between ages 14 and 60 years, followed by a rapid increase in damage for donors between 60 and 94 years of age (Barron et al., 2001). Preferentially, this mutation accumulated in the fovea and was linked with retinal dysfunctions observed in age-related maculopathies. Of note, while the Common Deletion increased in RPE with age for donors 34–88 years, it only increased in donors with advanced AMD, suggesting that this type of damage is not relevant to the early events in AMD pathogenesis (Karunadharma et al., 2010).

As AMD is per definition an age-dependent disease, the question whether it is associated with accelerated aging is often asked. Given the role of oxidative DNA damage in aging, the question about the role of mtDNA damage in AMD pathogenesis and its relations with aging also seems to be justified (Hyttinen et al., 2017). While the results obtained by Karunadharma et al. support the hypothesis that mtDNA damage increases with age, this damage was limited to the “Common Deletion” (Karunadharma et al., 2010). In contrast, the AMD-related mtDNA damage was distributed throughout the mitochondrial genome. These results suggest that AMD cannot be attributed only to accelerated aging, but it involves disease-specific changes that are superimposed on a background of typical age-related changes.

3. RPE mitochondria damage and dysfunction with AMD

With AMD, extensive changes to the mitochondrial genome have been reported. Comparison of mtDNA damage as measured by long-extension polymerase chain reaction (LX-PCR) in the macula of human donor RPE showed AMD donors had more mtDNA damage compared to the age-matched controls (Karunadharma et al., 2010; Terluk et al., 2015). Furthermore, the extent of RPE mtDNA damage correlated with AMD severity. Terluk and colleagues reported that the damage was localized in region of the mitochondrial genome that encode for the subunits of the ETC, thereby potentially leading to reduced ATP

production (Terluk et al., 2015). Damage was also observed in the D-loop, the only non-coding region of the genome that is the site of initiation for mtDNA transcription and replication of one mtDNA strand. Of note, the background mutation rate in the D-loop is about an order higher than in the remaining, coding part of the mitochondrial genome (Allio et al., 2017). Damage to either the D-loop or region encoding the ETC proteins could lead to negative functional outcomes for the mitochondria.

Other clinically relevant information from this study included the finding that mtDNA damage was not limited to the macula as RPE harvested from the peripheral region also exhibited an AMD-related increase in damage (Terluk et al., 2015). It is also important to note that the AMD-related increase in mtDNA damage was not observed in the photoreceptors. A potential explanation may be related to the cell-specific difference in the pathways utilized to generate energy. In contrast with the RPE, which rely on ROS-producing mitochondria, photoreceptors utilize aerobic glycolysis, a pathway that does not produce excessive ROS (Ames et al., 1992; Medrano and Fox, 1995; Yu and Cringle, 2005; Hurley et al., 2015; Fisher and Ferrington, 2018).

Studies addressing the role of damage to mtDNA in AMD pathogenesis have also measured mtDNA damage in peripheral blood as a surrogate measure of the retina. However, there is evidence that mtDNA damage in peripheral blood shows different susceptibility to DNA-damaging factors than the retinal counterpart. This hypothesis is supported by results from Kenney et al., where they compared the extent of mtDNA deletions and rearrangements in retina, choroid, and blood of individuals with AMD and control subjects (Kenney et al., 2010). They noted higher levels of mtDNA rearrangements and deletions in the retina than blood for both normal and AMD samples. In addition, these observations reveal increased genetic variation in both the coding portion of mtDNA and the D-loop. The authors postulate that damage to these elements may lead to dysfunctional mitochondria and a reduced number of mtDNA copies (Udar et al., 2009).

There are several critical limitations that should be recognized when results from mtDNA damage analysis are interpreted. When the extent of mtDNA damage is evaluated with LX-PCR, the amount of PCR product depends on the amount of undamaged versus damaged template that is available for amplification. Damaged templates include DNA base modifications and single or double strand breaks that stop the DNA polymerase. However, the main oxidative modification to DNA bases is 8-oxo-guanine (8-oxo-G), which does not inhibit the DNA polymerase, so the LX-PCR assay would not recognize this modification. DNA fragmentation also limits or even eliminates the ability to quantify the amount of damage. Another limitation is that the type of mitochondrial damage cannot be determined. It is also important to note that there is great diversity in both the number of mitochondria per cell as well as the number of mtDNA copies per mitochondria. Since the assay is only measuring an average of many mitochondrial templates, the results cannot inform about the damage within a single cell or the distribution of damage among all the cells sampled. While acknowledging these limitations for LX-PCR, no other method for routine evaluation of mtDNA damage is currently available.

In addition to mtDNA damage, other mitochondrial alterations directly related to AMD have been reported (Feher et al., 2006; Nordgaard et al., 2006; 2008). A transmission electron microscopy (TEM) analysis of human donor eyes affected by AMD showed a reduction in the number of mitochondria compared with age-matched controls with no AMD (Feher et al., 2006). In a proteomic analysis of the RPE, AMD-related changes were observed in the ATP synthase subunit that participates in oxidative phosphorylation (Nordgaard et al., 2008). The decrease in total ATP synthase subunits that coincides with the progression of AMD could lead to a malfunction of the ATP synthase complex. Since the ATP synthase complexes exist as oligomeric supercomplexes that maintain mitochondrial morphology and the mitochondrial membrane potential (Arselin et al., 2004; Bornhovd et al., 2006; Minauro-Sanmiguel et al., 2005), the decreased amount of

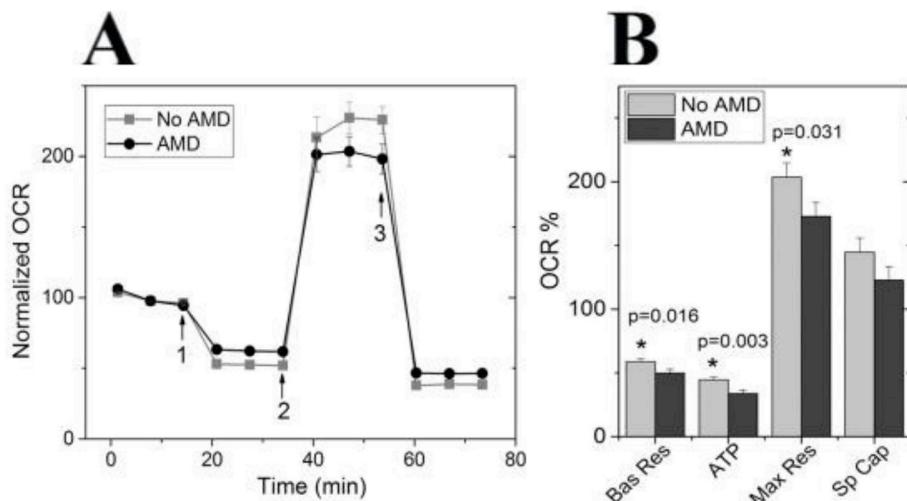

Fig. 3. RPE from donors with AMD show reduced mitochondrial function. (A) Trace from an XF96 Extracellular Flux Analyzer shows the oxygen consumption rate (OCR) normalized to baseline for cells from non-diseased and AMD donors (No AMD n = 14; AMD n = 19). Arrows indicate injection of oligomycin (1), FCCP (2) and antimycin and rotenone (3) to perturb mitochondrial function. (B) Mitochondrial functional parameters were calculated from data shown in A. Probability values for significant differences, as determined by t-test comparing No AMD with AMD, is provided on the graphs. Bas Res = basal respiration; Max Res = maximal respiration; Sp Cap = spare capacity. All data are mean (\pm SEM). (*) denotes $p < 0.05$. Data shown is similar to that in Ferrington et al. (2017), Redox Biol. publication.

the ATP synthase subunits with AMD could lead to defects in these critical processes. Another change in the mitochondrial proteome included the decline in the level of the mitochondrial heat shock protein (mtHsp70) observed in AMD RPE (Nordgaard et al., 2008). It functions as a molecular chaperone that regulates the ATP-dependent import of nuclear-encoded proteins into the mitochondrial matrix (Nordgaard et al., 2006, 2008; Kaarniranta et al., 2009). Therefore, decreased mtHsp70 levels could be detrimental to overall mitochondrial function and limit energy production in AMD.

Measurement of mitochondrial function in primary cultures of RPE provided direct evidence that energy production is significantly affected with AMD. Two different laboratories reported reduced mitochondrial function and ATP production in RPE cells isolated from human donors with AMD as compared with healthy subjects (Fig. 3, Ferrington et al., 2017; Golestaneh et al., 2017). Taken together, these results strengthen the hypothesis that mitochondrial damage and dysfunction may be involved in AMD pathology. Damage to RPE mitochondria associated with AMD not only decreased retinal bioenergetics, but could also disrupt intracellular calcium homeostasis and mitochondria-nuclear signaling, thereby having a more global impact on cell health (Rottenberg and Hoek, 2017; Fisher and Ferrington, 2018).

This section summarized the studies to date showing a significant increase in mtDNA damage is associated with normal aging and is more extensive with AMD. The next section discusses how disturbed mtDNA damage repair (DDR) may play a central role in the regulation of mitochondria function in AMD (Chinnery et al., 2002; Blasiak et al., 2013).

4. Mitochondrial DNA damage and repair in AMD pathogenesis

Human mtDNA contains 13 intron-less polypeptide-encoding genes and several shorter genes coding for functional RNAs, including 12S and 16S ribosomal RNA and 22 tRNA. Therefore, it is very likely that damage induced in mtDNA will be localized in a coding sequence corresponding with either the polypeptide-encoding genes or the RNA, thereby limiting the production of fully functional proteins. Since the genes encode for subunits of ETC, the main source of energy in the cell, their damage can result in serious consequences for cell energetics.

As discussed previously, the mitochondria generate ROS as a by-product of respiration. Therefore, mtDNA must be protected against damage or if damaged, must be repaired. Protection from ROS is provided by mitochondrial localized antioxidant enzymes, such as manganese superoxide dismutase (MnSOD), peroxiredoxins, catalase and glutathione peroxidases (GPXs): GPX1 and phospholipid-hydro-

peroxide GPX (PHGPX) (Holley et al., 2011). They neutralize ROS in a chain of reactions, in which MnSOD catalyzes the dismutation of superoxide radicals to hydrogen peroxide and molecular oxygen. Hydrogen peroxide is decomposed by peroxiredoxins that oxidize thioredoxin in this process. Hydrogen peroxide in mitochondria can be also removed by GPX1 and PHGPX. Previous research has reported a significant increase in both MnSOD and catalase in RPE from human AMD donors, suggesting the upregulation of these antioxidant enzymes was a compensatory response to the elevated oxidative stress induced by AMD (Decanini et al., 2007). Similar to nuclear DNA, which is protected from ROS damage by bound histones, nucleoid complexes of multiple proteins provide some physical protection to mtDNA from ROS-induced damage.

DNA damage elicits the response of a number of proteins that coordinate to repair the specific type of damage. This robust repair system in the nucleus includes: (i) base excision repair (BER) recovers damaged (oxidized, alkylated, hydrolyzed, deaminated) bases, (ii) nucleotide excision repair (NER) corrects lesions of double-stranded DNA (e.g., pyrimidine dimers), (iii) mismatch repair (MMR) removes unpaired nucleotides, (iv) non-homologous end-joining (NHEJ) and homologous recombination both repair double-strand breaks in genomic DNA (Zinovkina, 2018). There are substantial differences in the DNA repair systems operating in the nucleus and mitochondria (Table 1).

BER proteins involve DNA glycosylases (UNG1, MYH, OGG1, NEIL1/2), endonucleases (APE1, FEN1, EXOG1), the helicase DNA2 and DNA polymerase γ . While these enzymes are found in both the

Table 1

A comparison of the DNA repair systems operating in the nucleus and mitochondria of the human nucleated cells

Substrate	Repair system	
	Nucleus	Mitochondria
Chemical modifications to DNA bases	BER ¹⁾ , DR	
UV photoproducts	NER	?
Intrastrand crosslinks	NER	?
Interstrand crosslinks	HRR + NER + FAP	?
Mismatches, small loops	MMR	MMR (?)
Single-strand breaks	SSBR	?
Double-strand breaks	NHEJ, HRR, SSA	HRR, MMEJ, ?

Abbreviations used: BER, base excision repair; DR, direct repair; NER, nucleotide excision repair; HRR, homologous recombination repair; FAP, Fanconi anemia proteins; MMR, mismatch repair; SSBR, single-strand break repair; NHEJ, non-homologous end joining; SSA – single-strand annealing, MMEJ, microhomology-mediated end joining. The question mark indicates no evidence or uncertain occurrence.

mitochondria and nucleus, some have specific mitochondrial isoforms that are produced by alternative splicing. Other proteins that participate in BER include p53, which translocates into the mitochondria under conditions of oxidative stress where it interacts with DNA polymerase γ . Poly (ADP-ribose) polymerase (PARP1) is also involved in activation of the mitochondrial BER response to oxidative stress by interacting with DNA polymerase γ , transcription factor A mitochondrial (TFAM), and EXOG1.

Evidence for the presence of NHEJ, specifically the microhomology-mediated end joining (MMEJ), includes the mitochondrial localization of the main required enzymes, PARP1 and MRN (MRE11, Rad50-Nbs1)-CtIP complex (Zinovkina, 2018). Recently, biochemical evidence for the existence and activity of this pathway was provided (Tadi et al., 2016). Taken together, the presence of PARP1, active BER and MMEJ allows for repair of both single and double-strand breaks in mtDNA. While numerous enzymes from the other DDR pathways have been identified in the mitochondria, their exact function in this organelle is unknown or insufficiently studied. For example, the presence of some NER-related proteins in mitochondria suggests the possible action of NER, the most versatile pathway of DNA repair (Melis et al., 2013; Liu et al., 2015; Wu et al., 2018). Most but not all enzymes involved in homologous recombination are also present in the mitochondria, but to date, the existence of active recombination has not been definitively shown (Zinovkina, 2018). Thus, this area of research is being actively pursued due to the importance of DNA repair in health and disease.

Since accumulation of mtDNA damage is associated with normal and premature aging as well as serious human disorders, disturbed mtDDR may be involved in AMD (Fig. 1; Chinnery et al., 2002; Blasiak et al., 2013). While this possibility has not been extensively investigated, Lin et al. provides some evidence that mtDDR is reduced in aging and with AMD. Using cultured human RPE primary cells obtained from the macula and peripheral regions, they compared mtDNA damage and repair (Lin et al., 2011). While the extent of the damage in both regions increased with donor age, results show more damage to mtDNA in macular compared with RPE from the periphery. Moreover, efficacy of the repair of mtDNA damage decreased with age and was more reduced in macular compared with peripheral RPE. Heteroplasmic mtDNA mutations were more common in AMD than non-AMD eyes and were positively correlated with AMD severity. The authors concluded that defective mtDDR may be involved in AMD pathogenesis.

In summary, many reports point at mtDNA damage as an important contributing factor in AMD pathology (Fig. 1). Potential mechanisms responsible for the accumulation of mtDNA damage includes the decreased activity of antioxidant enzymes regulated by NFE2L2 and PGC-1 α , reduced mtDNA repair proteins, or disturbance in clearance of damaged mitochondria. Several reports claim that mtDNA is more prone to damage than its nuclear counterpart and some suggest that mtDNA damage in the retina preferentially occurs in the macula than in the periphery (Lin et al., 2011). Another problem in the mutagenesis of mtDNA is the assessment of efficacy of DNA repair enzymes (Caston and Demple, 2017). They all are encoded by the nuclear genome, and after transcription and translation, they must be imported into the mitochondria. The conclusion of DNA repair deficiency on the basis of lowered overall expression of DNA repair enzymes may therefore be an underestimate of the content of active enzyme localized within the mitochondria. Therefore, mtDDR in AMD should be subjected to further studies as its many aspects have been unequivocally shown to be changed in this disease.

5. Mitochondrial haplogroups and AMD

The effect of mitochondrial sequence polymorphisms that are found in different populations, referred to as haplogroups, has also been studied. Haplogroups are populations of individuals who share a common maternal ancestor and are defined by their similarity in mtDNA sequence. The letter names of the haplogroups run from A to Z, being

named alphabetically in the order of their discovery.

Several studies showed specific haplogroups demonstrated either a positive or negative association with AMD occurrence (Jones et al., 2007; Canter et al., 2008; SanGiovanni et al., 2009; Udar et al., 2009; Joachim et al., 2015). For example, the J haplogroup is linked with higher risk of AMD and the H haplogroup is linked with protection against this disease. A limitation of these reports is that they do not account for the influence of nDNA variants on the occurrence of AMD. To eliminate the impact of nDNA variants, Kenney et al. constructed cybrids using mitochondria-deprived ARPE-19 Rho0 cells merged with mitochondria from platelets of individuals belonging to either the H or J haplogroups (Kenney et al., 2013, 2014). In this experimental system, the nuclear genome was identical, but the cells contained the mitochondrial sequence that was specific for each haplogroup. They observed that J and H hybrids differentially expressed genes of the alternative complement pathway, inflammation, and apoptosis. J hybrids produced less ROS, had increased growth rate, and displayed a diminished expression of four genes involved in retinal degeneration as compared with their H counterparts. The authors also sequenced the entire mitochondrial genome to determine if rare mtDNA variants could be responsible for these results. They concluded that the changes they observed were not due to rare mtDNA variants, but rather to the mitochondrial genomic sequence associated with either the J or H haplogroup. These results show that the mitochondrial genome can significantly influence the expression of nuclear encoded genes, some clearly associated with increased risk for AMD.

6. Lipofuscin formation and monitoring in AMD

Lysosomes are key organelles that maintain the RPE-driven visual cycle (Sinha et al., 2016). They degrade phagocytosed photoreceptor outer segments (OS) in a circadian rhythm-controlled fashion via a process called heterophagy. The ROS formed due to constant light exposure, diurnal phagocytosis of lipid-rich OS, high retinal oxygen concentration and consumption, evoke malfunction of the lysosomes. Reduced capacity by lysosomes to degrade OS results in the accumulation of autofluorescent lipofuscin (Jarrett and Boulton, 2012). To date, it is largely accepted that lipofuscin is no longer only "normal age pigment", but it is rather an indicator of RPE cell stress and a key biomarker in AMD (Kaarniranta et al., 2010).

Lipofuscin can have an effect on RPE through disruption of multiple pathways. Detection of lipid peroxidation end-products i.e., highly reactive electrophilic aldehydes like malondialdehyde (MDA) and 4-hydroxynonenal (HNE) in lipofuscin suggests a connection between its formation and increased oxidative stress (Schütt et al., 2002; Schütt et al., 2003; Ye et al., 2016). Lipofuscin also contains vitamin A-derived fluorophores, including A2-E, that decrease both heterophagy and the mitochondrial capacity to produce energy in RPE cells (Vives-Bauza et al., 2008; Kaarniranta et al., 2013; Marie et al., 2018; Alaimo et al., 2019). A2-E is also a photosensitizer that decreases lysosomal enzyme activity and disturbs cholesterol metabolism (Holz et al., 1999; Bermann et al., 2001; Lakkaraju et al., 2007; Guha et al., 2014; Choudhary et al., 2016; Ban et al., 2018; Lu et al., 2018; Ramachandra Rao et al., 2018).

Lipofuscin can be monitored using non-invasive, very sensitive, cost-effective, and rapid autofluorescence-based imaging techniques, which have become very important in ophthalmology clinics. Although there are multiple heterogenic fluorescent complexes in the RPE, the highest autofluorescence intensity comes from lipofuscin (Dysli et al., 2017). Every fluorophore is characterized by its own excitation and emission wavelength spectrum and exhibits an individual fluorescence lifetime. The fluorescence intensity depends on the molecular environment and the fluorophore's concentration. The clinical equipment measuring fundus autofluorescence (FAF) has an excitation wavelength of 488 nm and an emission bandwidth of 500–700 nm. Lipofuscin can be detected in that wavelength range, but it also covers the fluorescence

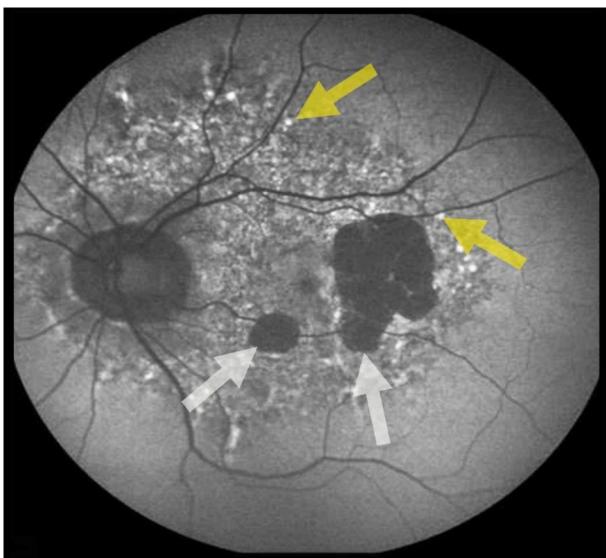

Fig. 4. Fundus autofluorescence (FAF) image from a patient suffering geographic atrophy (GA; white arrows) in advanced AMD. Yellow arrows indicate increased autofluorescence due to lipofuscin accumulation and drusen. Photograph by Kai Kaarniranta. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

of macular pigment, retinal carotenoids, different protein aggregates, and organelles. FAF shows an unspecific RPE cell emission, which is not only coming from lipofuscin. Therefore, the role of lipofuscin in AMD pathology may be difficult to determine based on FAF. However, FAF is very useful in clinics to do differential diagnosis for retinal diseases, since some of them have typical FAF characteristics, such as Stargardt's disease, central serous chorioretinopathy and retinitis pigmentosa. FAF may provide data from the lesions associated with aging, stress conditions, or toxic effects in RPE cells.

Clinically advanced dry AMD, referred to as geographic atrophy (GA), possess elevated FAF around the atrophic lesion (Fig. 4). Currently, there are critical differences in opinions regarding the toxicity and influence of lipofuscin on the progression of AMD (Holz et al., 2007; Rudolf et al., 2013; Fleckenstein et al., 2018). Holz et al. showed that distinct phenotypic FAF patterns correlated with dry AMD progression and thus might be used as a prognostic factor (Holz et al., 2007). The amount of FAF in RPE adjacent to GA lesions correlated with the spread of the atrophic area during subsequent follow-up visits. Rudolf et al. documented that FAF around GA did not predict cells undergoing death. This group found that the increased FAF around the lesions was due to vertically superimposed cells and cellular fragments (Rudolf et al., 2013). The amount of autofluorescence, cell density, and packing geometric analysis revealed the uncoupling of lipofuscin content and RPE or photoreceptors cell numbers in AMD (Ach et al., 2014). Redistribution and loss of autofluorescent granules were present in the earliest AMD changes (Ach et al., 2015), and decreased autofluorescence was in line with the increased severity of RPE dysmorphia (Gambril et al., 2019).

Altogether, the accumulation of fluorescent lipofuscin is a clinical hallmark of AMD. Lipofuscin reduces the lysosomal clearance capacity and increases cellular stress in RPE. FAF is used in clinics for diagnosis, differential diagnosis and following the progression of retinal diseases.

7. Mitochondria-lysosome axis in the regulation of protein clearance

Autophagy is a highly dynamic lysosomal catabolic process (Johansen and Lamark, 2020). It contributes to intracellular quality control and housekeeping that is extremely important in quiescent cells like RPE cells (Kaarniranta et al., 2013; Kim et al., 2013; Rodríguez-Muela et al., 2013). Autophagy may act at basal levels, but is activated

in response to environmental challenges. It is divided into non-selective and selective autophagy. Autophagy was initially characterized as non-selective bulk degradation that recycles amino acids and attempts to compensate for the lack of nutrients (Zaffagnini and Martens, 2016). Currently, we know that a selective autophagy is crucial by mediating the degradation of aggregated proteins, organelles, and invading pathogens (Johansen and Lamark, 2020). The molecular machinery for selective autophagy must ensure efficient recognition and sequestration of the cargo within autophagosomes. In selective autophagy particular substrate are targeted into the autophagosome by selective autophagy receptors.

Autophagy is divided into microautophagy, chaperone-mediated autophagy, and macroautophagy (Kaarniranta et al., 2013; Boya et al., 2016). Macroautophagy can be categorized into several selective types of autophagy according to their degradation targets, such as aggregates (aggrophagy), lipid droplets (lipophagy), exogenous pathogens (xenophagy), and organelles (for instance nucleophagy, ribophagy and mitophagy). Autophagy directs degradation of unnecessary or damaged cellular molecules and organelles by delivering them to lysosomes, in which they are then broken down by lysosomal hydrolytic enzymes (Fig. 5). Macroautophagy is mediated by the formation of a double membrane autophagosome. Cargo destined for degradation is sealed in autophagosomes and when combined with lysosomes, results in a structure called an autolysosome. Lysosomal enzymes degrade cargo.

Decreased autophagy capacity has been strongly linked to the pathology of AMD (Fig. 5; Wang et al., 2009; Kaarniranta et al., 2013; Viiri et al., 2013; Mitter et al., 2014; Valapala et al., 2014; Ferrington et al., 2016b). The RPE-specific autophagy knockout leads to cellular degeneration resembling AMD (Kim et al., 2013). Since lysosomal enzyme activity is crucial to autophagy flux, lipofuscin components may ultimately decrease autophagy clearance capacity. This statement is supported by reports showing impaired autophagy coincides with lipofuscin granules and drusen deposits in RPE cells (Karlsson et al., 2013; Mitter et al., 2014; Felszeghy et al., 2019). Additionally, a decline in autophagic capacity accompanied by an increase in ROS production can elicit protein aggregation and activation of inflammasomes in RPE cells (see section 13; Piippo et al., 2014, 2018). Conversely, another study showed that autophagy induction alleviates A2E-induced RPE damage and reduced production of inflammatory cytokines and vascular endothelial growth factor A (VEGFA; Zhang et al., 2015).

To avoid the vicious cycle of extensive ROS production with further mitochondrial damage and ROS release, dysfunctional mitochondria must be removed from cells via mitophagy, a specialized form of selective macroautophagy, where the main cargo are mitochondria (Fig. 6; Lemasters, 2005; Gurubaran et al., 2020). In selective autophagy, specific cargo is targeted and ubiquitinated, later followed by recognition by/through autophagy adaptor molecules, such as autophagy adaptor protein p62/SQSTM1, followed by autolysosomal degradation (Viiri et al., 2013).

Dysfunctional mitochondria and their exacerbated generation of ROS are among the earliest events in the progression of the numerous neurodegenerative diseases (Ratnayaka et al., 2007; Gureev and Popov, 2019). Since the maintenance of healthy mitochondria is essential to help RPE cells survival, dysfunction of this process in AMD can have harmful consequences. Under stress, both mitochondrial fission and fusion work together to maintain functional mitochondria (Kageyama et al., 2012). An increase in mitochondrial fission leads to mitochondrial fragmentation, whereas fusion results in mitochondrial elongation. Failure in any of the components of this machinery may lead to RPE degeneration (Brown et al., 2019). Once mitochondria are damaged, the inner membrane depolarizes and activates mitophagy, which does not always follow the canonical selective autophagy characteristics for clearance of protein aggregates (McWilliams et al., 2019). The PINK1-Parkin-derived pathway of mitophagy is commonly activated by ROS (Fig. 5; Hyttinen et al., 2018). First, the kinase PINK1 is stabilized in the outer mitochondrial membrane (OMM) after

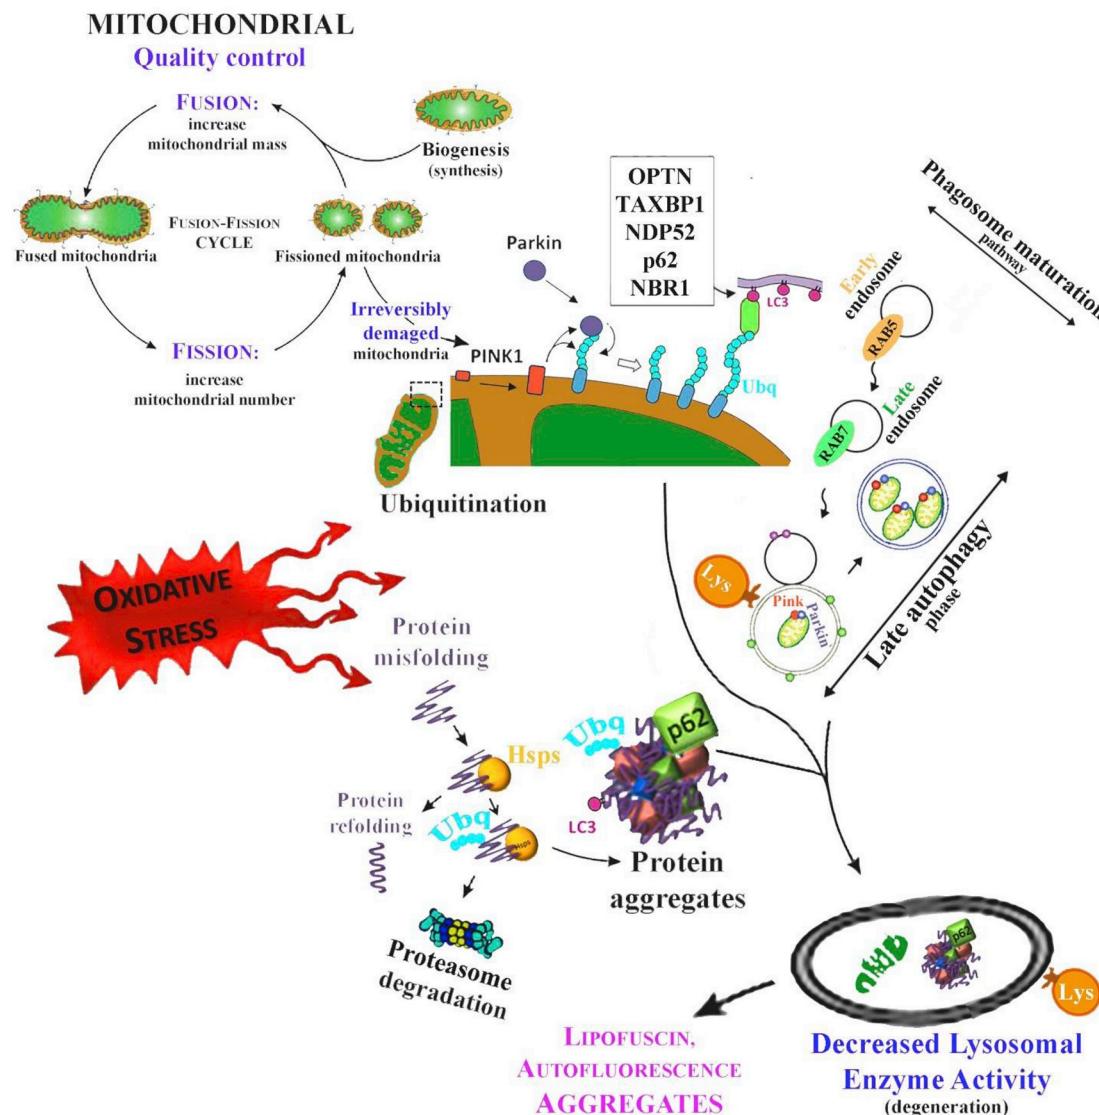

Fig. 5. The PINK1-Parkin-regulated mitophagy. Chronic oxidative stress and ROS evokes misfolding of proteins in RPE cells. Heat-shock proteins (Hsps) attempt to refold damaged proteins, but if not successful, the misfolded proteins are ubiquitinylated (Ubq) and targeted for proteasomal clearance. Once proteasome activity is decreased or its capacity exceeded, proteins start to aggregate and are degraded via autophagy. Mitochondrial damage results in the accumulation of PINK1 and the activation of Parkin. Mitophagy receptors, such as OPTN (optineurin), TAXBP1 (Tax-1-binding protein 1), NDP52 (nuclear domain 10 protein 52), p62 and NBR1 (Neighbor of BRCA1 gene 1 protein), and contains an ubiquitin-binding site that allows their attachment to Parkin-ubiquitinylated mitochondria. This process initiates the phagophore formation leading to sealed material degradation. Rab 5 and Rab7 control endosome maturation that finally leads to fusion of lysosomes and autophagosomes. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

mitochondrial membrane potential disruption followed by PARKIN (a cytosolic E3-ubiquitin ligase) phosphorylation, and finally ubiquitination. These processes initiate the isolation membrane formation around the damaged mitochondrion by selective autophagy receptors. OMM attach to autophagosomes via their microtubule-associated protein 1 light chain 3 (LC3) interacting region (LIR) motifs. One group of mitophagy receptors contains an ubiquitin-binding domain, which allows its attachment to Parkin-ubiquitinylated mitochondria, p62/SQSTM1, NBR1 (Neighbor of BRCA1 gene 1 protein), NDP52 (nuclear domain 10 protein 52), AMBRA1 (activating molecule in Beclin1-regulated autophagy), TAX1BP1 (Tax1 binding protein 1) and OPTN (optineurin) (Zaffagnini and Martens, 2016; Johansen and Lamark, 2020). During maturation, members of the Rab family (Ras-related guanosine triphosphate-binding proteins) and SNAREs complex (soluble N-ethylmaleimide-sensitive factor attachment protein receptors) control lysosome and autophagosome fusion process (Nakamura and Yoshimori, 2017; Gurubaran et al., 2020). Rab proteins are important regulators of vesicular transport. Rab7 binds to autophagosome membrane and

regulates late-state fusion with the enzymatic lysosomes (Fig. 5; Hyttinen et al., 2013). Receptor-mediated mitophagy, also known as PINK1/Parkin-independent pathway, contain transmembrane domains and upon expression they constitutively localize to OMM. The LIR motif activity of mitophagy receptors is regulated by phosphorylation for binding to Bnip3 (BCL2 interacting protein 3), Nix/Bnip3L (BCL2-like 3), FUNDC1 (FUN14 domain containing 1) and Bcl2L13 (BCL2-like 13), FKBP8 (FK506-binding protein 8), PHB2 (prohibitin 2), NLRX1 (Nod-like receptor X1), AMBRA1, cardiolipin and ceramide that enhance mitophagy (Gurubaran et al., 2020; Johansen and Lamark, 2020).

The loss of mitochondrial membrane potential is one of the mitophagy-inducing signals (Azad et al., 2009; Twig and Shirihai, 2011). The induction of mitophagy triggered by rotenone, which blocks the complex I in ETC (Lee et al., 2014), is in line with the idea of the protective role of mitophagy in RPE cells and inversely, of destructive consequences upon dysfunctional intracellular clearance (Hyttinen et al., 2018). Interestingly, NFE2L2, a ROS sensor, can regulate the expression of PINK1 due to four AU-rich elements (ARE) in the

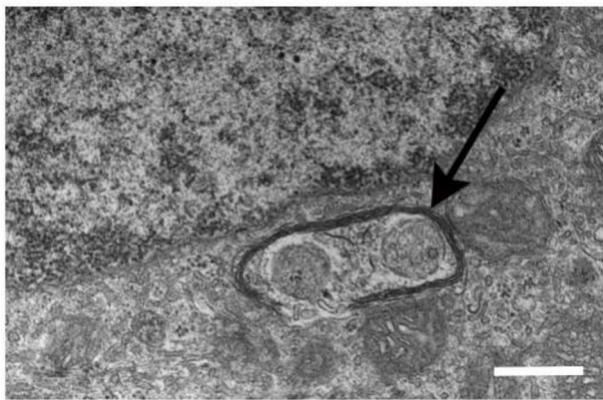

Fig. 6. A transmission electron micrograph shows damaged mitochondria enclosed by an autophagosome (arrow) in the RPE of a 20-month-old Cryba1 knockout mouse. The scale bar = 500 μm. The electron micrograph has been modified from the Sinha et al. (2016) *Exp. Eye Res.* publication.

promoter of the corresponding gene (Murata et al., 2015). Therefore, there is evidence that activation of NFE2L2 can directly regulate mitophagy.

Mouse models with genetic manipulation of gene expression for proteins involved in mitochondrial maintenance (PGC-1α), antioxidant response (PGC-1α, NFE2L2), or lysosomal acidification (Cryba1) have provided valuable insight into their effect on mitophagy (Sinha et al., 2016; Felszeghy et al., 2019; Gurubaran et al., 2020). Our data reveal that the deficiency in *NFE2L2/PGC-1α* and *Cryba1* genes, relatively to increased oxidative stress, decrease mitophagy in mouse RPE cells. Recently, it was demonstrated that p62/SQSTM1 is able to bind directly to ubiquitinated mitochondrial OMM proteins (Lazarou et al., 2015). p62/SQSTM1 is recruited to mitochondrial clusters and is essential for the clearance of mitochondria in Parkin-dependent mitophagy (Geisler et al., 2010). p62/SQSTM1 expression is also controlled by NFE2L2 due to the presence of ARE in its promoter region (Jain et al., 2010). It seems that NFE2L2 and PGC-1α are central proteins in the regulation of selective autophagy in RPE cells.

8. NFE2L2 in mitochondrial quality control

NFE2L2/NRF2 is the key transcription factor in the sensing of oxidative stress (Lambros and Plafker, 2016). NFE2L2 is sometimes designated as NRF2, which can be missed with nuclear respiratory factor 2 (NRF2), which functions as a transcription factor activating the expression of key metabolic genes regulating cellular growth and nuclear genes required for mitochondrial respiration, DNA transcription, and replication (Baldelli et al., 2013). NFE2L2 was found to associate with the outer mitochondrial membrane and protect mitochondria from oxidant injury likely through direct interaction with mitochondria (Figs. 7 and 8; Strom et al., 2016). Upon activation, NFE2L2 is released from NFE2L2-KEAP1 (kelch-like ECH-associated protein 1) and the mitochondrial outer membrane serine/threonine protein phosphatase 5 (PGAM5) complex, allowing for the translocation of NFE2L2 from the cytosol into the nucleus. NFE2L2 can bind to an ARE to promote the transcription of more than 200 genes, including detoxification and anti-oxidant enzymes (heme oxygenase-1 (HO-1), NAD(P) H:quinone oxidoreductase-1 (NQO1), sulfiredoxin-1 (SRXN1), superoxide dismutase 2 (SOD2), PGAM5, per-oxiredoxins 3 and 5 (PRDX3 and PRDX5)), and enzymes involved in GSH metabolism (glutathione S-transferases, glutathione-synthesizing enzymes glutamate-cysteine ligase catalytic subunit (GCLC) and glutamate-cysteine ligase modifier subunit (GCLM)) (Silhola and Levonen, 2017; Silva-Palacios et al., 2018; Di Malta et al., 2019).

Under basal conditions, cytosolic KEAP1 functions as an adapter for the E3 ubiquitin ligase and constitutively targets NFE2L2 for ubiquitylation and degradation via the ubiquitin proteasome system (UPS)

(<http://cancerres.aacrjournals.org/content/79/5/889.long>; Kobayashi et al., 2004). However, in oxidative stress a conformational change in KEAP1 structure prevents the degradation of NFE2L2 by the proteasome. *De novo* synthesized NFE2L2 accumulates and translocates to the nucleus where it heterodimerizes and subsequently activates AREs. Since NFE2L2 also activates proteasomes and lysosomal autophagy, it regulates the quality control of proteins via the removal of misfolded and ubiquitinated proteins and damaged cellular organelles (Dick, 2017). It has been shown that the depletion of NFE2L2 disturbs mitochondrial motility, which is linked to degenerative diseases like AMD (Sachdeva et al., 2014; O'Mealey et al., 2017). Common NFE2L2-KEAP1 pathway induction and subsequent stimulation of the antioxidant response is estimated to prevent or slow the progression of degenerative and immunological processes and thus promote longevity (Murray et al., 2018).

High mitochondrial ROS production, combined with impaired antioxidant systems, results in detrimental protein aggregation (Scherz-Shouval et al., 2007; Korovila et al., 2017). Recently, impaired proteolysis in response to chronic oxidative stress has been suggested as a key contributor in AMD (Ferrington et al., 2016b). The proteasome and the lysosomal'autophagy degradation systems share the major responsibility of maintaining cellular proteostasis (Blasiak et al., 2019). Both systems recognize and actively select the material designated for degradation and recycling in cells. Degradation of damaged and misfolded proteins via the proteasome occurs in coordination with molecular chaperones (Ferrington et al., 2016b). Evidence of increased content of proteasome and heat shock proteins in the RPE from human donors with AMD is consistent with increased oxidative stress and extensive protein damage with this disease (Decanini et al., 2007). The proteasome degrades 80–90% of cellular proteins in eukaryotes, including short-lived, abnormal, denatured or damaged soluble proteins (Ciechanover, 2012). This proteolytic system also controls processes essential for cell viability, cell-cycle regulation, signal transduction, synaptic plasticity, pigmentation and circadian regulation (Juuti-Uusitalo et al., 2017; Gureev and Popov, 2019). Prior to degradation by the proteasome, the 76-amino acid ubiquitin polypeptide is covalently attached to the protein substrate via the ubiquitin-activating (E1), ubiquitin-conjugating (E2) and the ubiquitin ligase (E3) enzyme. Accumulated ubiquitin levels can be used as an surrogate indicator of the capacity of proteasomes to degrade damaged proteins. Data that suggests a decline in proteasome capacity with AMD, includes the increased ubiquitin levels in drusen localized under the macula from donors with AMD (Fig. 2E; Mullins et al., 2000; Viiri et al., 2013). In our NFE2L2/PGC-1α dKO mouse model of AMD, levels of protein ubiquitination were significantly increased in both RPE and photoreceptors (Fig. 8; Felszeghy et al., 2019).

In addition to basal homeostasis, autophagy increases in cellular stress conditions, which often coincides with the induction of the NFE2L2 pathway (Chen and Maltagliati, 2018). Beneficial effects of NFE2L2 pathway activation and autophagy induction have been recognized in cellular stress responses. For example, polyunsaturated fatty acids transiently increase ROS, and induce both NFE2L2 and autophagy (Johansson et al., 2015). These cellular changes coincide with decreased damage in RPE cells (Wang et al., 2014a, 2016a; Johansson et al., 2015; Kaarniranta et al., 2019). Other compounds with similar properties studied in RPE include isothiocyanate sulforaphane (O'Mealey et al., 2017), dimethyl fumarate (Lastres-Becker et al., 2016), triterpenoid derivatives RS9, RTA408 and gycyrrhizin (Liu et al., 2016; Saito et al., 2018; He et al., 2019), carotenoids fucoxanthin, lutein, lycopene, zeaxanthin and astaxanthin (Li et al., 2013; Zou et al., 2014; Yang et al., 2016; Frede et al., 2017), flavonol compounds fisetin and pinosylvin, (Hytti et al., 2015, 2017; Koskela et al., 2014), adenosine monophosphate kinase (AMPK) activators PF-06409577 and AICAR (5-aminoimidazole-4-carboxamide ribonucleoside) (Viiri et al., 2013, Li et al., 2018; Marchesi et al., 2018) are shown in Table 2. Isothiocyanate sulforaphane, lutein, zeaxanthin and AMPK activation effectively

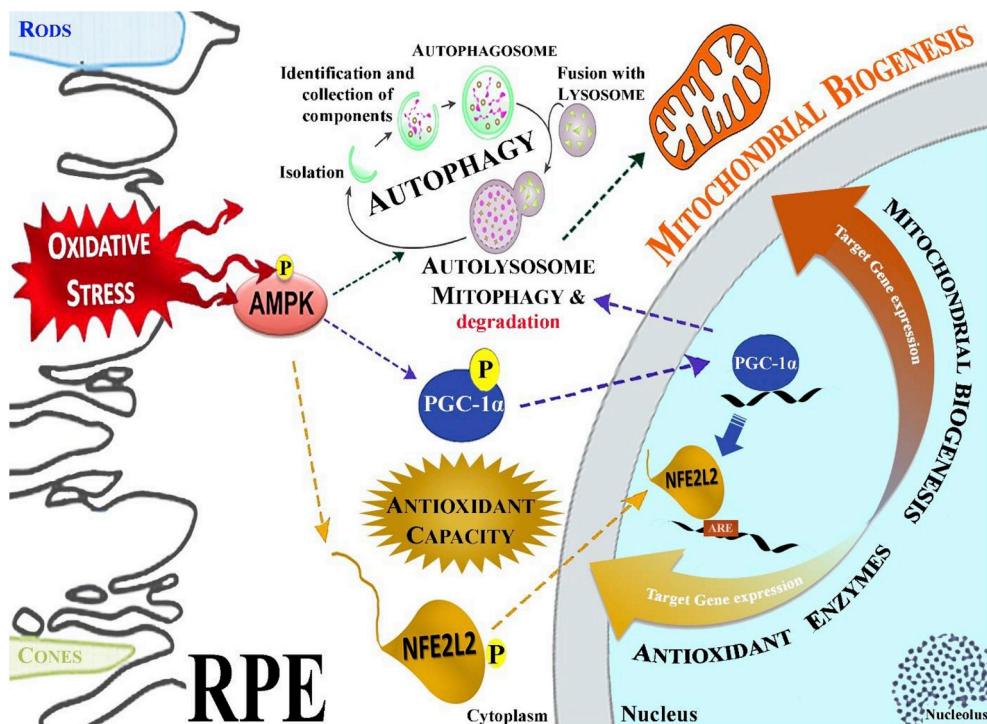

Fig. 7. Schematic presentation of the oxidative stress influence on AMPK, NFE2L2, PGC-1 α , and autophagy pathway interactions in RPE. In response to oxidative stress, AMPK is phosphorylated, which subsequently phosphorylates NFE2L2 and PGC-1 α leading to their nuclear translocation and activation of genes that regulate mitochondrial biogenesis and antioxidant protein production. NFE2L2 and PGC-1 α also have a key role in the regulation of autophagy. Failure in AMPK-mediated signaling leads to disturbed proteostasis in RPE cells.

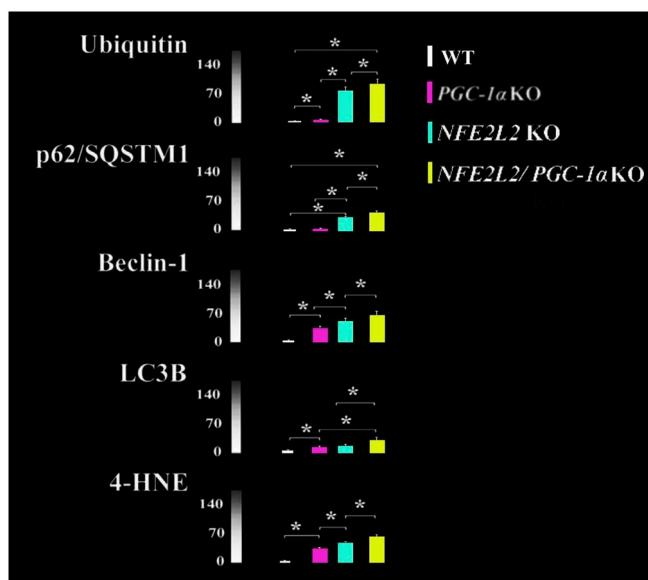

Fig. 8. Increased protein aggregation (Ubiquitin), autophagy (p62/SQSTM1, Beclin-1, LC3B) and oxidative stress (4-HNE) markers in the RPE cells of PGC-1 α KO, NFE2L2 KO and NFE2L2/PGC-1 α dKO mice. Data represent average intensities from three different animals per genotype and $n = 30$. * $p < 0.001$ one-way ANOVA followed by Games-Howell post hoc test. Results are expressed as means \pm SD. Columns represent similar results shown in the Felszeghy et al. (2019) Redox Biology publication.

protects mitochondria under oxidative stress in RPE cells (Zou et al., 2014; O'Mealey et al., 2017; Su et al., 2014; Xu et al., 2018). Correspondingly, the deficiency of NFE2L2 in our mouse model results in reduced autophagic flux that may be due to impaired lysosomal enzyme activity (Figs. 7 and 8; Krohne et al., 2010; Dayalan Naidu et al., 2017; Felszeghy et al., 2019). It is important to note that we did not block autophagy flux with the specific autophagy inhibitors in our animal models (Klionsky et al., 2016). The use of autophagy flux inhibitors are more commonly used in cell culture conditions. Our interpretation for

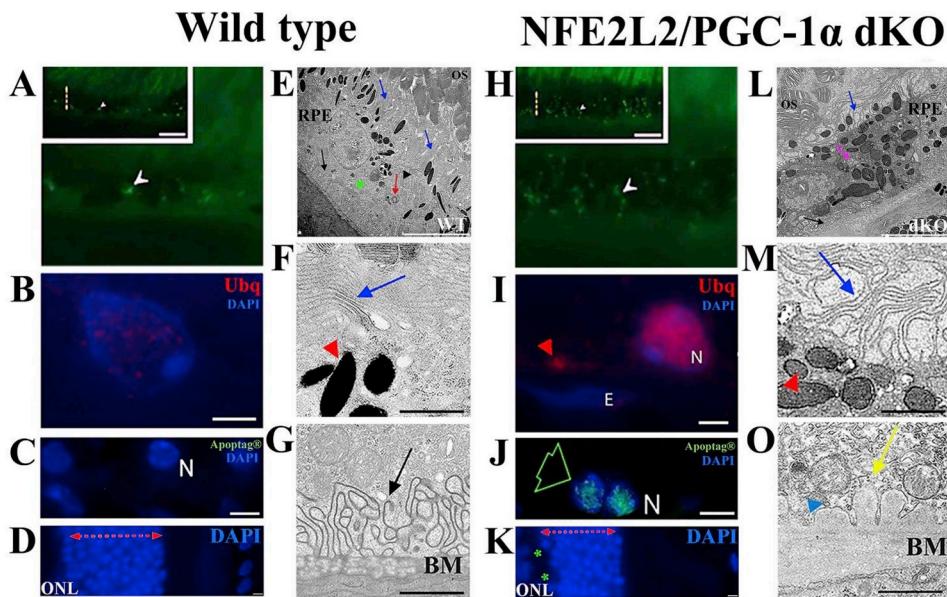

the decreased autophagy flux *in vivo* is based on the reduced number of autophagolysosomes in TEM and the increased autophagy markers in confocal micrographs (Felszeghy et al., 2019). Similar autophagy marker analysis has been used in *ex vivo* retina studies (Gómez-Sintes et al., 2017).

Proteasomal and autophagy clearance are connected via the scaffolding adaptor protein p62/SQSTM1 (Jain et al., 2010). p62/SQSTM1 is a multifunctional protein that undergoes phosphorylation prior to binding with ubiquitin and LC3 and subsequent degradation of protein aggregates, malfunctioning mitochondria, and pathogens in autophagosomes (Seibenhener et al., 2004; Matsumoto et al., 2011; Myku and Figueiredo-Pereira, 2011). Proteasome inhibition induced ubiquitinated protein aggregates are degraded by autophagy in human RPE cells (Viiri et al., 2010, 2013). In line with accumulated ubiquitinated protein conjugates, p62/SQSTM1 accumulates in RPE cells of AMD donors having drusen maculopathy, suggesting suppressed proteasomal and autophagy activity (Viiri et al., 2013). In addition to autophagy regulation, p62/SQSTM1 stabilizes NFE2L2 through its binding with KEAP1, blocks the Keap1-NFE2L2 interaction, and activates the expression of genes having AREs (Lau et al., 2010; Komatsu et al., 2010). SQSTM1/p62 promotes autophagic degradation of KEAP1 and the activation of the NFE2L gene response. This forms a positive feedback loop for the activation of NFE2L2 via autophagy-related SQSTM1/p62 in response to oxidative stress (Ichimura and Komatsu, 2018; Shah et al., 2018). Moreover, NFE2L2 positively regulates p62/SQSTM1 gene expression, implying a positive feedback loop (Jain et al., 2010).

Various autophagy-related genes (Atg) have ARE sequences in their promoter regions, and several of these genes are known to be regulated by NFE2L2, including: Unc-51 like autophagy activating kinase (ULK1; autophagy initiation) p62/SQSTM1 (cargo recognition), Atg7 and gamma-aminobutyric acid receptor-associated protein-like 1 (GABAR-APL1; autophagosome formation), Atg2B and Atg5 (elongation), and Atg4D (autolysosome clearance) (Wang et al., 2007; Pajares et al., 2016). Our recent observations show an increase in NFE2L2 gene activity and subsequent upregulation of ROS-induced proteins that prevent damage has been found in RPE cultures from AMD donor eyes (Ferrington et al., 2017). Moreover, our data indicate that the marker of oxidative stress, 4-HNE, as well as autophagy markers p62/SQSTM1,

Table 2
NFE2L2 activators.

Compound	Effect	Model	Reference
Isothiocyanate sulforaphane	Activates KEAP-NFE2L2-ARE pathway Inhibits mitochondrial fission	RPE-1 cells	O'Mealey et al. (2017)
Dimethyl fumarate	NFE2L2 activator Neuroprotection	Primary microglias	Lastres-Becker et al. (2016)

AICAR	Activates autophagy Decreases protein aggregation	ARPE-19 cells	Viiri et al. (2013) Marchesi et al. (2018)

are more visible in dKO. N means nuclei and E endothelial cell nuclei. The scale bars for A, H = 5 μm, B, I and I-K = 2 μm, C, J = 5 μm, D, K = 2 μm, E,L = 5 μm, F, M and G, O Data represent similar results shown in the Felszeghy et al. (2019) Redox Biology publication. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

Beclin-1 and LC3 and protein aggregation marker ubiquitin were significantly elevated in *NFE2L2* KO compared to *PGC-1α* KO mice suggesting oxidative stress, insufficient proteasome function and autophagic clearance (Fig. 8). *NFE2L2/PGC-1α* double knockout (dKO) mice had the highest accumulation of all markers studied compared with single KO, suggesting the dKO mice had the most extensive oxidative stress and greater defects in the proteasome/autophagy clearance

(Felszeghy et al., 2019). Ultrastructural analysis indicated an increased ratio of the damaged and healthy mitochondria in dKO RPE cells. We also observed that the dKO has larger autolysosomes, reduced basal infoldings and a moderate increase in lipofuscin level compared to intact normal cell structures in WT RPE cells (Fig. 9). Additionally, the number of melanosomes was higher in dKO mice. Moreover, Bruch's membrane elastic and collagenous layers were not often observed, and

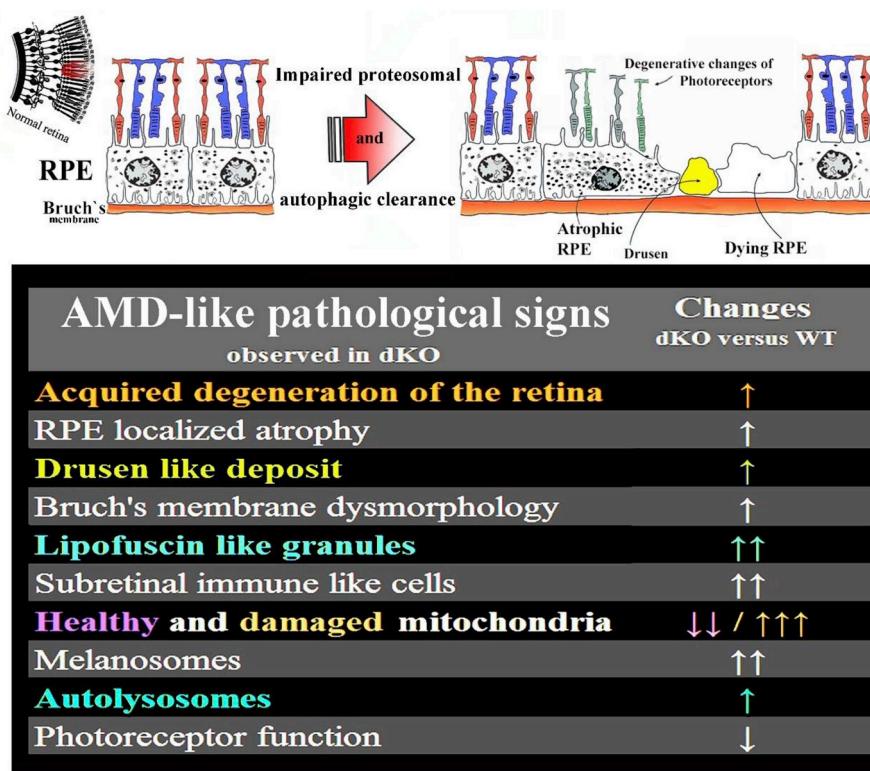

Fig. 10. Graphical summary of the AMD hallmarks detected in one-year-old NFE2L2/PGC-1 α gene modified mice. Summary modified from the Felszeghy et al. (2019) Redox Biology publication.

increased thickness of Bruch's membrane was detected along with an accumulation of electron dense amorphous material in dKO animals.

Data from human donor eyes reveal that during AMD development, many cytoprotective mechanisms are first upregulated, including anti-oxidant production, molecular chaperone production, and improved clearance. Once the disease shifts to the chronic state, cytoprotection is followed by a decreased capacity to respond to stress. Our recent studies in mouse models suggest that the most promising target for pharmacological intervention on mitochondria is the NFE2L2 signaling cascade (Figs. 7 and 8). The rationale for this statement includes that NFE2L2 participates in the maintenance of mitochondrial homeostasis, which is provided by an optimal ratio in the processes of mitochondrial biogenesis and mitophagy, as well as the optimal ratio of ROS production and ROS scavenging. As shown previously, NFE2L2 activators are capable of modulating these processes and maintaining mitochondrial homeostasis in neurons (Gureev and Popov, 2019). Since, the RPE is composed of quiescent cells, they could be a viable option for treating AMD patients early in the disease.

9. PGC-1 α in mitochondrial quality control

The peroxisome proliferator-activated receptor gamma coactivator-1 (PGC-1) family consists of PGC-1 α , PGC-1 β and PRC (PGC-1-related coactivator). These proteins control mitochondrial biogenesis, respiratory function, and the mitochondrial antioxidant defense system. PGC-1 α enhances RPE metabolic functions and resistance to oxidative stress through the induction of oxidative metabolic genes, antioxidant enzymes, and regulating autophagy (Fig. 8; Egger et al., 2012; Roggia and Ueta, 2015; Iacovelli et al., 2016; Felszeghy et al., 2019; Rosales et al., 2019). Deficiency of PGC-1 α increases mitochondrial damage, as well as the oxidative stress markers 3'-nitrotyrosine and 4-HNE (Lu et al., 2010; Felszeghy et al., 2019.). The activation of the energy sensor AMPK induces autophagy and regulates PGC-1 α activities (Jäger et al., 2007; Viiri et 2013; Marchesi et al., 2018). Revealing the importance of

PGC-1 α in the pathogenesis of AMD, iPSC-derived RPE cells isolated from dry AMD patients showed decreased PGC-1 α expression (Golestaneh et al., 2016).

Our global KO mouse models for PGC-1 α exhibited dry AMD-like degenerative signs but were not as extensive as that observed with NFE2L2 or NFE2L2/PGC-1 α deficiency (Figs. 8 and 10; Felszeghy et al., 2019). However, data from Ferrington's lab indicate that primary RPE cells isolated from AMD donors expressed higher levels of PGC-1 α and were more resistant to oxidative stress (Fig. 3, Ferrington et al., 2017). This reveals the capacity of RPE cells to respond to increased oxidative stress by different defense systems as we have previously documented (Decanini et al., 2007; Viiri et al., 2013). Individual genetic variations and severity of AMD may affect RPE stress responses (Kaarniranta et al., 2018a,b). Recent papers indicate that PGC-1 α is required to maintain the functional and phenotypic status of RPE by supporting the cells' oxidative metabolism and autophagy-mediated repression of epithelial-mesenchymal transition (Zhang et al., 2018; Rosales et al., 2019). PGC-1 α cooperates with p53 to attenuate the effects of oxidative stress and its consequences for mitochondria (Kaarniranta et al., 2018a).

The PGC-1 α promoter contains consensus sequences recognized by NFE2L2 (St Pierre et al., 2006). PGC-1 α and NFE2L2 have overlapping functions in promoting the mitochondria protective response (Fig. 8; Baldelli et al., 2013). Similar to NFE2L2, PGC-1 α induces expression of several genes coding for antioxidant enzymes, such as SOD2, SOD1, Gpx1 and uncoupling proteins (UCP1/2) thus giving mechanistic evidence for their overlapping functions in the regulation of the anti-oxidant system (Baldelli et al., 2013; Ježek et al., 2018). Notably, NFE2L2 expression is controlled by PGC-1 α suggesting a feed-forward loop promoting expression of protective genes, thereby amplifying the effect. The activation of the PGC-1 α /NFE2L2 loop increases the activity of the proteasome and autophagy leading to decreased protein aggregation, a characteristic of aging and neurodegenerative diseases. Our PGC-1 α and NFE2L2 KO mice support this evidence since they both show increased ubiquitinated protein conjugates, lipofuscin- and

drusen-like aggregate formation, relatively impaired autophagy flux, and recruitment of inflammatory cells (Felszeghy et al., 2019). All these effects suggest altered protein-organelle quality control in RPE cells, which has been suggested to contribute to AMD (Ferrington et al., 2016b). Mitochondrial quality control may be improved by AMPK, which is a master regulator of autophagy and mitophagy. Sirtuin 1 (SIRT1) phosphorylation by AMPK leads to deacetylation and activation of the PGC-1 α . AMPK is a putative pharmacological target in the prevention of neurodegenerative inflammatory disease (Kaarniranta et al., 2018a; Salminen et al., 2012).

10. Mitochondrial dysfunction in the induction of inflammation

Increasing evidence reveals that protein damage and aggregation induce inflammation in AMD (Anderson et al., 2010; Ferrington et al., 2016b; Chen et al., 2019). Para-inflammation is a beneficial host defense that can be shifted to chronic inflammation, which is associated with the pathological processes of advanced AMD. Inflammation is a rapid response to factors endangering cellular homeostasis, such as damaged macromolecules, dysfunctional mitochondria, as well as prolonged oxidative stress (Shadrach et al., 2013; Mao et al., 2014; Kauppinen et al., 2016). Currently, it is well known that mitochondrial damage and ROS production induce inflammation by activating the NOD-like receptor family, pyrin domain containing 3 (NLRP3) signaling pathway in RPE cells (Kauppinen et al., 2012; Shi et al., 2015; Wang et al., 2016b, 2017). Due to aging and AMD pathology, autophagy and antioxidant systems decline, resulting in the accumulation of damaged mitochondria and its subsequent harmful effects, such as ROS production and inflammasome activation (Zhou et al., 2011; Lee et al., 2012; Datta et al., 2017). Degenerating RPE cells with dysfunctional autophagy and mitochondria are recognized as dangerous material in the tissue since they can induce inflammasome activation in surrounding macrophages (Liu et al., 2016a; Wang et al., 2019). On the other hand, extensive autophagy evokes cell death in RPE, subsequently triggering cytokine production in macrophages (Szatmári-Tóth et al., 2016; Szatmári-Tóth et al., 2019). Additionally, specific haplogroups arising from inherited variation in mitochondrial DNA can participate in the pathogenesis of AMD, e.g., through altered complement functions and their predisposition to promote inflammasome signaling (Kenney et al., 2013, 2014; Malik et al., 2014; Atilano et al., 2015, Gao et al., 2015). Finally, challenges to mitochondrial function have been shown to result in changes in nuclear inflammatory genes expression and the development of the “inflamm-aging” RPE cell phenotype (Miceli and Jazwinski, 2005; Cannizzo et al., 2011; Salminen et al., 2012).

Mitochondria can contribute to inflammation in multiple ways. Inflammasome activation is stimulated by ATP, oxidized mtDNA, or cardiolipin (Kauppinen et al., 2016). Furthermore, mtDNA-induced toll-like receptor 9 (TLR9) activation promotes interferon regulatory factor 3 (IRF3)-mediated type I interferon (IFN) release, the production of inflammatory cytokines through nuclear factor-kappa B (NF- κ B) or the mitogen mitogen-activated protein kinase (MAPK)-mediated signaling following mtDNA-activated cyclic guanosine monophosphate-adenosine monophosphate synthase/stimulator of interferon genes (cGAS/STING) pathway, and formyl peptide-driven chemotaxis (Bader and Winklhofer, 2019). Of those, especially inflammasome signaling and the mtDNA-mediated cGAS/STING pathway, activation have been implicated in RPE cells as mitochondria-related mediators of inflammation. mtDNA-driven NF- κ B or MAPK activation, as well as ATP-regulated P₂Y₁ receptor signaling are also able to implement the priming signal for the inflammasome activation in RPE cells (Prager et al., 2016; Doktor et al., 2018; Fann et al., 2018). NF- κ B p65 activity may be a critical upstream initiator of p62/SQSTM1 expression in RPE cells under oxidative stress that links inflammatory signaling to autophagy and NFE2L2 cascades (Song et al., 2017). Furthermore, Advanced Glycation End (AGE) product activates NF- κ B and renders it more responsive to pro-inflammatory stimuli and extracellular matrix

modifications in RPE cells (Kay et al., 2014; Sharif et al., 2019).

Recent reviews discuss the role of NOD-Like, Toll-Like, AGE product receptors, pentraxins, and complement system in AMD pathology (Kauppinen et al., 2016; Kaarniranta et al., 2019). Accelerated recycling of the membrane-bound complement regulator CD59 to the RPE cell surface inhibits the late activation of complement cascade. Once complement attack occurs, fusion of lysosomes with the RPE plasma membrane suppresses elevations in intracellular calcium and prevents mitochondrial injury (Tan et al., 2016). Disturbances in CD59 recycling and lysosome exocytosis may lead to mitochondrial fragmentation and increased ROS production in RPE. Complement factor B deficiency and smoking extract induced oxidative stress evoked increase in a RPE size that can be interpreted as a prognosis factor of cell death (Woodell et al., 2013; Chen et al., 2016). Evidence of inflammation was also present in mouse models exhibiting an AMD-like phenotype. Deficient NFE2L2 induces a pro-inflammatory environment by generating C3a and C3b in response to smoking (Wang et al., 2014b). *NFE2L2/PGC-1 α* dKO mice exhibited significantly increased ionized calcium binding adaptor molecule 1 (Iba-1) mononuclear phagocyte marker and enlarged RPE size (Felszeghy et al., 2019).

The accumulation of *Alu*-retroelement RNA or DICER1 deficiency are known to drive mtDNA release from RPE cells through mitochondrial permeability transition (MPT) pores (Kerur et al., 2018). By interacting with cGAS, mtDNA promotes noncanonical NLRP3 inflammasome activation by caspase-4 in human and caspase-11 in mouse (Tarallo et al., 2012; Kerur et al., 2018). cGAS, IFN- β and caspase-4 are among factors that have been found in increased amounts in the eyes of dry AMD patients (Kerur et al., 2018). The cGAS pathway is important in viral resistance, but it has recently been associated also with the pathogenesis of chronic diseases, including AMD (West et al., 2015; Kerur et al., 2018). In addition to MPT and BAX/BAK pores, mtDNA can escape from mitochondria also within mitochondrial-derived vesicles. It has been hypothesized that mtDNA may be released from the endo-lysosomal pathway or from autophagosomes due to incomplete destruction of engulfed mitochondria and thereby end up in the cytosol where it can activate the NLRP3 inflammasome (Bader and Winklhofer, 2019).

Taken together, insufficient autophagy elevates the amount of damaged mitochondria and ROS production in AMD. Chronic oxidative stress coincides with the detrimental signaling effects of Toll-Like, AGE product receptors, pentraxins, complement system and inflammasomes.

11. Future directions

Mitochondria are organelles essential for maintaining RPE cell function. However, over the course of aging, mitochondria exhibit decreased rates of oxidative phosphorylation, increased ROS generation, and increased amounts of mtDNA damage and mutations (Murphy, 2009; Kageyama et al., 2012). Mitochondria in RPE are particularly susceptible to oxidative damage with aging and especially in pathological processes like those occurring in AMD (Núñez-Álvarez et al., 2019). While inflammation has been a therapeutic target in various clinical trials to treat AMD, outcomes have been relatively poor. Since mitochondria are connected to the regulation of cytoprotection, proteolysis, and inflammation, they might be a promising therapeutic target in early stages of AMD development.

Humanin (HN), a member of a family of mitochondrial-derived peptides, is expressed from an open reading frame of mitochondrial 16S ribosomal RNA (rRNA) (Matsunaga et al., 2016; Sreekumar et al., 2016). Humanin exhibits cytoprotective properties against oxidative stressors (e.g. by activating autophagy pathway, inhibiting ROS generation, upregulating mitochondrial GSH and activation of caspases 3 and; Minasyan et al., 2017; Gong et al., 2018). The mechanism behind humanin's cytoprotective properties likely involves activation of AMPK (Yong and Tang, 2018).

We have previously shown that AMPK activator AICAR also exhibits

cytoprotective properties by accelerating protein clearance in RPE via autophagy (Viiri et al., 2013; Marchesi et al., 2018). AMPK has a pleiotrophic role in the protection of mitochondria. It can stimulate mitochondrial biogenesis through increasing the gene transcription regulated by PGC-1 α and can acutely trigger the destruction of existing defective mitochondria through ULK1-dependent mitophagy. Moreover, it is the key player in activating NFE2L2 signaling cascades and anti-oxidant production. Thus, AMPK has the net effect of replacing existing defective mitochondria with new functional mitochondria. The agonist of AMPK has cytoprotective effects by reducing detrimental protein aggregation in RPE cells (Salminen et al., 2012).

Our enhanced understanding of mitochondrial dysfunction in dry AMD pathogenesis may lead to the development of targeted therapies. However, defects in multiple biological pathways leading to different AMD phenotypes suggest that one type of treatment for all AMD patients may not be universally effective in the preventing or reversing the disease. One can predict that personalized medicine will increase in clinics not only in follow-ups and treatments, but also for selecting patients and planning clinical trials to find optimal endpoints (Barot et al., 2011). Targeting to correct mitochondrial dysfunction in the RPE, an essential factor in AMD pathology, is a viable option. Therefore, the aim in AMD therapy is to find drugs that better control mitochondria fusion/fission balance and/or activates autophagy to remove damaged mitochondria (Osborne et al., 2014; Kaarniranta et al., 2018c). One can estimate that this strategy could include the suppression of chronic oxidative stress and inflammation in the RPE (Kaarniranta et al., 2018c). In addition to new drug candidates and therapeutic targets, there are demands to develop longer-lasting agents or new drug delivery systems (Del Amo et al., 2017; Nashine et al., 2018; Schottler et al., 2018; Sharma et al., 2018; Popov, 2019). Possible breakthroughs in AMD treatments may open new therapeutic options in other retinal diseases.
