Abstract

ST-elevation myocardial (STEMI) is frequently associated with conduction disorders. Regional myocardial ischemia or injury may affect the cardiac conduction system at various locations, and neural reflexes or changes in the balance of the autonomous nervous system may be involved. Sinoatrial and atrioventricular block are more frequent in inferior than anterior STEMI, while new left anterior fascicular block and right bundle branch block indicate proximal occlusion of the left anterior descending coronary artery. New left bundle branch block is associated with multi-vessel disease.

Most conduction disorders associated with STEMI are reversible with reperfusion therapy, but they may still impair prognosis, because they indicate a large area at risk, extensive myocardial infarction or severe coronary artery disease.

Acute STEMI recognition is possible in patients with fascicular or right bundle branch block, but future studies need to define the cut-off values for ST depression in the leads V1-V3 in inferolateral MI and for ST elevation in the same leads in anterior STEMI. In left bundle branch block, concordant ST elevation is a specific sign of acute coronary artery occlusion, but the ECG feature has low sensitivity.

Keywords: Conduction disorder, acute coronary syndrome, acute myocardial infarction, bundle branch block, atrioventricular block, pacemaker

List on acronyms

ACS = acute coronary syndrome
AV = atrioventricular
HDAVB = high degree atrioventricular block
IAB = interatrial block
LAD = left anterior descending artery
LAFB = left anterior fascicular block
LBBB = left bundle branch block
LCX = left circumflex artery
LSFB = left septal fascicular block
MI = myocardial infarction
PCI = percutaneous coronary intervention
RBBB = right bundle branch block
RCA = right coronary artery
SA = sinoatrial
STEMI = ST-elevation myocardial infarction
TIMI = Thrombolysis In Myocardial Infarction
UDMI = Universal Definition of Myocardial Infarction
Bradyarrhythmias

Sinoatrial block

Sinus bradycardia is frequent in acute inferior ST-elevation myocardial infarction (STEMI), especially during the first hours after occlusion of the coronary artery [1, 2]. Sinus bradycardia was three times more common in inferior than in anterior acute myocardial infarction (MI) [3]. Bradycardia may be caused by depressed automatism. The Bezold-Jarisch reflex includes a triad of bradycardia, hypotension and vasodilation, and inferior wall myocardial ischemia may elicit this reflex [4]. The reflex is thought to result from the stimulus of cardiopulmonary mechanoreceptors that are associated with unmyelinated vagal afferent nerve fibers, classified as C-fibers. The sinoatrial (SA) nodal side branch (or artery) originates from the right coronary artery (RCA) in about two thirds (Fig. 1) and from the left circumflex artery (LCX) in about one fifth of individuals [5]. The side branch may also take off directly from the aorta. Very proximal occlusion of the RCA caused by thrombus or aortic dissection may result in occlusion of the SA nodal branch, but occlusion may also result from stenting over the side branch ostium or from embolization. Ischemia of the cardiac conduction system may be the result of these pathophysiological processes.

SA nodal branch occlusion may result in sinus bradycardia, sinoatrial block or even asystole. Because the SA nodal branch also irrigates parts of the atrial walls, bradycardia may be accompanied by atrial MI. In practice, it is not possible to distinguish between abnormalities in impulse formation, impulse conduction, or a combination, in the standard 12-lead ECG in patients with intermittent absence of sinus P waves. In sinus bradycardia and SA block, vagally induced bradycardia will disappear with atropine while ischemic bradycardia persists.

Serrano et al compared inferior STEMI patients based on the culprit artery and the level of occlusion [2]. Sinus bradycardia in the admission ECG was noted in 15% of the patients with RCA occlusion, but in none of the patients with LCX occlusion, and proximal RCA occlusion was more often associated with sinus bradycardia than mid or distal occlusion.

Interatrial block

Interatrial block (IAB) is a distinct ECG pattern caused by conduction delay between the right and left atrium, probably resulting from local fibrosis reflected in the surface ECG as a biphasic
morphology of the P wave in the inferior leads (II, III, aVF) [6, 7]. This together with a P-wave duration ≥120 ms is considered as advanced IAB. P-wave duration ≥120 ms with normal P-wave morphology is defined as partial IAB. In STEMI patients (n=198) without a history of atrial arrhythmias treated successfully with primary percutaneous coronary intervention (PCI), about half of the patients had partial or advanced IAB at presentation, while six hours after PCI, the prevalence of IAB had decreased to one quarter [8]. RCA stenosis and diffuse coronary artery disease were associated with IAB at admission. Partial IAB on admission and six hours post-PCI were independent predictors of atrial fibrillation at 12-month follow-up. In a registry study (n=972) of STEMI patients in sinus rhythm at hospital discharge, 21.3% had partial and 5.9% advanced IAB [9]. Patients with IAB had higher all-cause mortality than patients without IAB, but the association was explained by older age and other variables, while the multivariable analysis did not show any independent association between IAB and prognosis. In patients (n=109) undergoing elective PCI of the RCA or LCX, atrial branch occlusion was associated with more frequent intra-atrial conduction delay, atrial tachycardia and atrial fibrillation [10]. After adjustment by a propensity score, atrial branch occlusion was an independent predictor of periprocedural infarction and atrial arrhythmias. The authors speculated that atrial ischemic episodes might be considered as a potential cause of atrial fibrillation in patients with coronary artery disease.

Atrioventricular block

Atrioventricular (AV) block is a rather frequent finding in acute inferior STEMI. This is partly explained by the fact that the side branch to the AV node takes off distally from the posterolateral branch of the RCA (Fig. 2). In left-dominant circulation, the AV nodal branch arises from the LCX. The mechanism of AV conduction disturbance in acute STEMI is different depending on the infarct location. In a recent study of STEMI patients, RCA culprit predicted second degree Mobitz 2 or third-degree AV block (high degree AV block, HDAVB) with an odds ratio of 3.80 [11]. RCA occlusion increases acetylcholine release from the myocardium of the inferior wall, and this contributes to the AV block. As for ischemia of the AV node, vagal overdrive disappears following the administration of intravenous atropine, while AV block of ischemic origin persists. Ischemic AV block usually presents fast heart rate, while vagally induced block does not [12]. According to Lie et al, in patients with acute inferior MI and HDAVB, escape beats of left bundle branch block (LBBB) morphology
represent conducted beats (AV junctional escape beats), while those with right bundle branch block (RBBB) morphology most probably represent fascicular of ventricular escape rhythm requiring pacemaker implantation [13].

Mobitz 1 (Wenckebach) second-degree AV block is most frequent in inferior STEMI caused by RCA occlusion, and it is usually transient and supra-Hisian, while Mobitz 2 -block is usually infra-Hisian and implies worse prognosis. In infra-Hisian Mobitz 2 -block, the PQ-interval prolongation is usually mild, or the PQ interval may even be normal [12, 14].

The prognostic implications of third-degree (complete) AV block depends on the STEMI location. When it occurs in association with inferior STEMI, it usually evolves from a first-degree block, the QRS complex is narrow and the block is supra-Hisian [12]. Advanced AV block presenting in an anteroapical infarction is usually accompanied by an infra-Hisian escape rhythm with a wide QRS complex, which may result in hemodynamic deterioration. In this scenario, pacemaker implantation is indicated, but the outcome of the patient is dependent on the extent of the infarction and the degree of left ventricular dysfunction. In inferior STEMI, advanced AV block is more often seen in patients with terminal QRS distortion (Sclarovsky-Birnbaum grade III ischemia) than in those with grade II ischemia in the leads with ST-segment elevation [15].

Berger et al reported a 19% incidence of second- or third-degree AV block in acute inferior MI by combining results from studies published in the 1960’s - 1980’s [16]. In the recent HORIZONS-AMI trial, where almost all 3,115 study STEMI patients had primary PCI, HDAVB was found in 1.5% of the patients [11]. Of the patients with HDAVB, 60.9% had a temporary pacemaker implanted in the catheterization laboratory. The incidence of HDAVB in a recent national survey from 2010 was 2.1% [17]. In a recent large STEMI registry study (n=16,536), the incidence of HDAVB was 6.6% in inferior STEMI, but only 0.3% in anterior STEMI [18]. In a recent study of 4,799 patients with acute coronary syndrome (ACS) (STEMI in 55.7%), 1.9% presented with complete AV block [19].

HDAVB has been associated with an increased risk for in-hospital complications and higher mortality rates during follow-up; in the old study by Berger et al, mean in-hospital mortality rate was 23% [16]. In the recent HORIZONS-AMI study, 30-day mortality in HDAVB was 8.8% compared with 2.3% (p=0.005) in the patients without HDAVB.

In ACS patients with complete AV block in the previously mentioned publication by Aguiar Rosa et al, 79.1% had inferior STEMI compared with 21.9% in the patients without complete AV block,
and in-hospital mortality was almost eightfold higher in patients with complete AV block (23.1% vs. 3.5%) [19]. In the large STEMI registry study referred to previously, anterior, but not inferior location was associated with increased in-hospital mortality in HDAVB patients after multivariate adjustment [18].

The HORIZONS-AMI investigators also studied the incidence and prognostic implications of worsening AV block post-primary PCI [20]. They reported a 1.5% progression of both second and third degree AV block after one year. Anterior STEMI was associated with worsened AV block, which was an independent predictor of all-cause death and major adverse cardiac events. The authors speculated that HDAVB probably was the result of chronic damage to the AV conduction system, related to left anterior descending (LAD) coronary artery culprit lesions associated with extensive myocardial injury or infarction, in these patients.

*Which patients need a temporary pacemaker?*

Although AV block associated with inferior STEMI is usually temporary, benign and nearly always resolves with reperfusion therapy, intermittent pacemaker therapy may be necessary in case of hemodynamic compromise or bradycardia-related ventricular arrhythmias. According to the 2017 ESC Guidelines for the management of acute myocardial infarction in patients presenting with ST-segment elevation, temporary pacing is required in cases of sinus bradycardia with hemodynamic intolerance or HDAVB without stable escape rhythm if the arrhythmia does not respond to positive chronotropic medication [21]. AV sequential pacing should be considered in patients with complete AV block, right ventricular infarction, and hemodynamic compromise. According to the 2013 ACCF/AHA STEMI guidelines, temporary pacing is indicated for symptomatic bradyarrhythmias unresponsive to medical treatment, and application of transcutaneous pacing pads for potential use is reasonable treatment in HDAVB caused by inferior STEMI [22]. Prophylactic placement of a temporary pacing system is recommended for HDAVB in patients with anterior/lateral MI.

*Intraventricular block*

*Fascicular block*
The presence of a new left anterior fascicular block (LAFB) associated with anterior STEMI strongly supports a culprit artery location in the proximal part of the LAD, because the left anterior fascicle receives its blood supply from the first major septal branch of the LAD [23]. The development of LAFB in the course of an inferior infarction (RCA or LCX occlusion) indicates concomitant significant stenosis of the LAD before the first major septal branch.

The appearance of left posterior fascicular block, which causes clear rightward deviation of the frontal plane QRS axis, is extremely rare in STEMI patients, and they are typically published as case reports. The left posterior fascicle is the least vulnerable division of the intraventricular conduction system. Compared with the left anterior fascicle, the left posterior fascicle is larger, has faster demand repolarization, receives its blood supply from two coronary systems (the LAD and the RCA, and runs through a more protected area, the left ventricular inflow tract with less mechanical pressure impact [24]. Transient rightward shift of the frontal QRS axis in patients with acute anterior MI has been associated with severe two- or three-vessel disease, typically with collateral circulation between the LAD and the RCA [25]. Ischemia of the left posterior fascicle was suggested as the etiologic factor.

The existence of a tetrafascicular intraventricular conduction system, including a left septal fascicle, remains debatable. A consensus statement ended up with some discrepancies and, despite agreeing on the possible existence of an anatomical left septal fascicle, the electrocardiographic and vectorcardiographic characteristics of left septal fascicular block (LSFB) were not universally accepted [7]. The most important criteria to indicate the existence of LSFB is its intermittent nature, because other causes of prominent anterior QRS forces, such as right ventricular hypertrophy, septal hypertrophy, lateral wall myocardial infarction, and lead switch have to be considered in the ECG diagnosis. The proposed ECG criteria for LSFB include normal or slightly increased (up to 110 ms) QRS duration, R-wave voltage of V1 ≥ 5 mm, R wave of V2 > 15 mm, and absence of a q wave in the left precordial leads V5, V6 and in lead I [26]. Two case reports from patients with ST-elevation ACS, one with anterior and one with inferior ST elevation, and prominent anterior forces, indicating LSFB, were reported [27, 28].

Right bundle branch block

The right bundle branch receives its blood supply from an anterior septal branch of the LAD alone or jointly with the AV nodal artery [29]. Therefore, a proximal LAD occlusion may result in a new
RBBB, which is often accompanied by LAFB, because the right bundle branch and the left anterior fascicle receive essentially the same blood supply (Fig. 3). RBBB + LAFB is a type of bifascicular block. These intraventricular blocks are mostly reversible with reperfusion therapy.

Transient RBBB in inferior STEMI is rare, and is probably explained by ischemia of the proximal His bundle, selectively inhibiting conduction to the right bundle branch; the His bundle is dually supplied by the AV nodal branch (proximal His bundle) and the first septal branch of the LAD (distal His bundle) [14, 29].

RBBB and LAFB was demonstrated in more than half of the patients with acute total left main occlusion in a small patient series (Fig. 4) [30]. In addition, there was typically ST-segment elevation in the precordial leads from V2 to V4-6 and in leads I and aVL, accompanied by ST-segment depression in the inferior leads.

A unique situation occurs when LAFB obscures RBBB, abolishing the terminal S waves in leads I and aVL and the terminal R (R’) wave in V1 [31]. The existence of a RBBB is indicated by a broad QRS, wide R’ in lead aVR and a wide S wave in leads V5 and V6.

RBBB does not interfere with the diagnosis of acute STEMI, and the ECG criteria for STEMI are the same as for patients with a narrow QRS. Diagnosing ST elevation in the anterior, inferior and lateral leads can easily be done in patients with RBBB. However, the diagnosis of inferolateral STEMI equivalent in patients with RBBB and baseline ST depression in V1-V3 is a challenge, and prospective studies are needed to define the threshold for ST deviations in this setting. In acquired RBBB, there is typically an initial Q wave, while in pre-existing RBBB, there is rRS’ configuration [14] (Fig. 3 and 4).

RBBB was associated with increased mortality in acute MI patients in a meta-analysis, which included a considerable proportion of acute STEMI patients [32]. A radical change has recently taken place in the treatment recommendations for patients with new or presumably new RBBB and a suspicion of acute MI. The Fourth Universal Definition of Myocardial Infarction (UDMI) states: “New, or presumed new, RBBB without associated ST-segment or T wave changes is associated with thrombolysis in myocardial infarction (TIMI) 0–2 flow in as many as 66% of patients (compared with >90% in those with ST-segment or T wave changes)” [33]. The 2017 ESC guidelines for STEMI also specify: “Patients with myocardial infarction and RBBB have a poor prognosis. It may be difficult to detect transmural ischaemia in patients with chest pain and RBBB. Therefore, a primary percutaneous coronary intervention strategy (emergent coronary angiography and percutaneous coronary intervention if indicated) should be considered when
persistent ischaemic symptoms occur in the presence of RBBB” [21]. These recommendations are mainly based on a retrospective study by Widimsky et al [34]. That study included 6,742 patients with AMI and showed that among the 427 patients with RBBB (53% with concomitant ST elevation), TIMI 0 flow in the infarct related artery was found in 51.7%, and primary PCI was performed in 80.1% of the patients. TIMI flow 0 in the infarct-related artery was found in significantly more patients with new or presumably new RBBB (55%) than in the group with old RBBB (34.9%), old LBBB (28%) or new or presumably new LBBB (41.1%). It is somewhat surprising that also RBBB without ST elevation has been added as a STEMI equivalent ECG manifestation in the new guidelines. The study results by Widimsky et al apply to patients with adjudicated acute MI, not necessarily to patients in the emergency care settings, and not all study patients underwent emergent angiography according to a primary PCI protocol. Significant coronary artery lesions in patients with RBBB are not necessarily new culprit lesions. Therefore, outcome data are needed in patients with chest pain, presumably new RBBB and no significant ST deviation treated with or without primary PCI. Also the usefulness of primary PCI for patients presenting with RBBB and atypical symptoms (shortness of breath, acute heart failure, etc.) should be prospectively tested.

A more recent article by Neumann et al included 4,067 patients with suspected acute MI [35]. RBBB was found in 3.1% of the patients, and of them, only 20.8% had a final diagnosis of acute MI (six had STEMI and 17 non-ST elevation MI). Mortality for patients with RBBB at 1-year follow-up was 10.7% compared to 3.2% in the patients without broad QRS. The study data challenge the concept of RBBB as an indication for emergent coronary angiography, as the likelihood of MI was similar to that of patients without bundle branch block.

Another clinical point related to RBBB is, whether a lower threshold for ST elevation than for narrow QRS should be used in anterior STEMI because of the baseline secondary ST depression in the right precordial leads associated with this conduction disorder. Future studies should address this issue, and also the cut-off values for ST depression in the leads V1-V3 in inferolateral MI need to be established.

Left bundle branch block

The left bundle branch is a larger and less vulnerable structure than the right bundle branch. The blood supply to the left bundle branch is clearly of dual origin as the anterior fascicle is supplied
mainly by anterior septal branches of the LAD and the posterior fascicle from the AV nodal artery, which originates from the RCA or the LCX depending on coronary artery dominance. Accordingly, severe two- or three-vessel disease should typically be present for a new LBBB to develop.

Sgarbossa et al introduced three criteria to help in identifying acute MI in patients with LBBB [36]. They were: (1) ST-segment elevation ≥1 mm and concordant with the QRS complex (5 points); (2) ST-segment depression ≥1 mm in leads V1, V2 or V3 (3 points); and (3) ST-segment elevation ≥5 mm and discordant with the QRS complex (2 points). A total score of three or more points was considered diagnostic of acute MI, whereas a score of 2 points suggests an acute MI. A meta-analysis reported the Sgarbossa criteria to be specific (98%) but with low sensitivity (20%) [37]. Concordant ST elevation has proved to be the single most specific criterion for the diagnosis of acute MI in the presence of LBBB, and improves the detection of this “STEMI equivalent” [38] (Fig. 5). An adaptation of the Sgarbossa criteria, including ST-elevation to S-wave ratio may be too complicated for use in the emergency setting [39]. Also, serial ECG recordings may be helpful for acute MI diagnosis in patients with acute chest pain or equivalent and LBBB [40].

In a study from the Minneapolis Heart Institute STEMI protocol (n=3,903), new or presumably new LBBB was present in 3.3% of the patients [41]. The LBBB patients were older, more commonly women, with a lower ejection fraction, and more often presented with cardiac arrest or heart failure than those without new LBBB. The patients with new LBBB had fewer culprit arteries (54.2% vs. 86.4%, p<0.001), but at one-year follow-up they had higher all-cause mortality. The authors tested a hierarchical algorithm based on hemodynamic instability and Sgarbossa concordance criteria. The algorithm yielded high sensitivity (97%) and negative predictive value (94%) for identification of a culprit lesion, while specificity was 48%.

Another study from the US reported new or presumably new LBBB in 69/802 (8.6%) patients in the hospital primary PCI laboratory activation database [42]. Less than 30% of the patients with new or presumably new LBBB had troponin elevation, and 54% underwent emergent coronary angiography. Of these, 22% had a culprit vessel occlusion, while the emergent revascularization rate was 11.6%.

In a recent large registry study of patients with a definite diagnosis of acute MI, crude in-hospital mortality of patients with LBBB was 16.2% versus 6.5% for patients with STEMI [43]. The patients with LBBB were older, with a greater burden of risk factors and comorbidity, and they were less likely to receive medication and invasive therapy.
In patients (n=8,830) with suspected acute MI, LBBB was present in 2.8%, and of these 30% had a final MI diagnosis, with similar incidence in those with known LBBB vs. those with presumably new LBBB [44]. ECG criteria had low sensitivity (1%–12%) but high specificity (95%–100%) for acute MI. The study showed that combining ECG criteria with high sensitive troponin testing allows early and accurate diagnosis of acute MI in LBBB.

The fourth UDMI states: “In patients with LBBB, ST-segment elevation ≥1 mm concordant with the QRS complex in any lead may be an indicator of acute myocardial ischemia” [31]. The conclusion was that since the detection of ischemia by the ECG in LBBB is difficult, decisions concerning urgent reperfusion therapy should be based mainly on symptoms and hemodynamic parameters.

According to the 2013 ACCF/AHA STEMI guidelines, “New or presumably new LBBB has been considered a STEMI equivalent. Most cases of LBBB at time of presentation, however, are “not known to be old” because of prior electrocardiogram (ECG) is not available for comparison. New or presumably new LBBB at presentation occurs infrequently, may interfere with ST-elevation analysis, and should not be considered diagnostic of acute myocardial infarction (MI) in isolation” [22]. The 2017 ESC STEMI guidelines specify: “In the presence of LBBB, the ECG diagnosis of acute myocardial infarction is difficult but often possible if marked ST-segment abnormalities are present. Somewhat complex algorithms have been offered to assist the diagnosis, but they do not provide diagnostic certainty. The presence of concordant ST-segment elevation (i.e. in leads with positive QRS deflections) appears to be one of the best indicators of ongoing MI with an occluded infarct artery. Patients with a clinical suspicion of ongoing myocardial ischaemia and LBBB should be managed in a way similar to STEMI patients, regardless of whether the LBBB is previously known. It is important to remark that the presence of a (presumed) new LBBB does not predict an MI per se”. [20].

Hence, recognition of an impending acute myocardial infarction in patients with LBBB remains a challenge. Decision making regarding emergent coronary angiography cannot be based solely on 12-lead ECG findings. Clinical presentation, and probably also, sensitive troponin testing are important additional clinical tools.

Conclusions
STEMI is frequently associated with conduction disorders. SA and AV block are more frequent in inferior than anterior STEMI, while new LAFB and RBBB indicate proximal occlusion of the LAD. Most conduction disorders associated with STEMI are reversible with reperfusion therapy, but they may still impair prognosis, because they indicate a large area at risk, extensive myocardial infarction or severe coronary artery disease.
