Azobenzene Photoswitching with Near-Infrared Light Mediated by Molecular Oxygen

Kim Kuntze, Jussi Isokuortti, Antti Siiskonen, Nikita Durandin, Timo Laaksonen, and Arri Priimagi*

ABSTRACT: Efficient photoisomerization between the cis and the trans states of azobenzenes using low-energy light is desirable for a range of applications in, e.g., photobiology yet challenging to accomplish directly with modified azobenzenes. Herein, we utilize molecular iodine as a photocatalyst to induce indirect cis-to-trans isomerization of 4,4′-dimethoxyazobenzene with 770 nm near-infrared light, showing robustness during more than 1000 cycles in ambient conditions. Intriguingly, the catalysis is mediated by molecular oxygen, and we demonstrate that other singlet-oxygen-generating photosensitizers besides iodine, i.e., palladium phthalocyanine, catalyze the isomerization as well. Thus, we envision that the approach can be further improved by employing other catalysts with suitable photoelectrochemical properties. Further studies are needed to explore the applicability of the approach with other azobenzene derivatives.

INTRODUCTION

Molecular iodine is known to catalyze organic reactions when illuminated with visible light. The list of iodine-photocatalyzed reactions includes the oxidation of tertiary amines, allylic and benzylic alcohols, and styrenes into the respective aldehydes and has recently been extended with the degradation of trichlorophenol and selected intra- or intermolecular metal-free coupling reactions. In most reactions, the catalytic activity is attributed to iodine radicals formed in the homolysis of the I–I bond, presumably after initial excitation to \( \text{I}_2 \). In some cases, iodine is involved in energy transfer (TET). Even though excitation inside the therapeutic optical window (>650 nm) would be greatly beneficial for biological applications, no studies on iodine catalysis using red or near-infrared light excitation have been performed.

An important photochemical reaction that iodine is known to photocatalyze is the cis–trans isomerization of azobenzenes, a photoswitch family utilized in photoresponsive pharmaceuticals, catalysts, and materials. These applications benefit from precisely controlled light-driven isomerization, preferably with low-energy (red/near-infrared) light. Unfortunately, the lifetime of the metastable cis isomer is typically short for red-light-absorbing azobenzenes, an undesired feature in most applications. This deficiency can be addressed by synthetic modifications, especially ortho substitution with certain moieties that stabilize the cis isomer and in some cases separate the low-energy \( n-\pi^* \) absorption bands of the isomers, allowing selective trans–cis and cis–trans photosomerization with visible light. These bands are, however, limited to wavelengths below 600 nm with low molar absorptivity in the red end of the visible spectrum. Suitable photocatalysts offer an alternative pathway to control the photoswitching with low-energy irradiation. Azobenzenes...
have a short-living triplet state whose excitation leads mainly to trans-azozenes via rapid intersystem crossing.\textsuperscript{22,36–42} Thus, with a suitable triplet sensitizer it is possible to accelerate the cis–trans isomerization using significantly longer wavelengths than those absorbed by the azobenzene.\textsuperscript{38,43} However, isomerization via TET suffers from sensitivity toward oxygen, hampering the functionality of the systems in ambient conditions. If the redox potentials of the cis-azozenes and the sensitizer are matched, photoinduced electron transfer (PET) becomes feasible, and both reductive\textsuperscript{44} and oxidative\textsuperscript{45} PET processes have been used to drive the isomerization with wavelengths as long as 660 nm in the latter case. Despite recent progress in the field, iodine-catalyzed photoisomerization has not been studied since the first reports in the 1960s and 1970s. Therein, either 545 nm green light excitation of iodine or ultraviolet light excitation of a charge transfer complex between iodine and azobenzene was utilized, neglecting the possibility of low-energy-light excitation.\textsuperscript{21,22} Yet iodine would be highly attractive for this purpose because of its low cost, nontoxic nature, environmental friendliness, and, above all, the potential of catalyzing the isomerization in response to NIR light in ambient conditions. In this study, we set out to explore the photocatalytic properties of molecular iodine with the aim of controlling the azobenzene isomerization with low-energy light while also broadening the utility of molecular iodine in other photocatalytic processes.

\section*{RESULTS AND DISCUSSION}

Initially, we restricted our studies to the moderately electron-rich 4,4′-dimethoxyazobenzene (1) that has a relatively stable cis isomer (half-life 13 h) and has been found to isomerize efficiently with triplet sensitizers and photoinduced electron transfer agents without considerable fatigue.\textsuperscript{45} Solvents with nucleophilic electron pairs blue shift the absorption spectrum of iodine, so we studied the isomerization in three inert solvents of varying density and polarity: dichloromethane (DCM), carbon tetrachloride (TCM), and n-hexane (hexane). First, we recorded and analyzed the absorption spectra of 1 and iodine separately and in one solution (Figure 1). The absorption spectrum of trans-1 is governed by an intense band at ca. 370 nm, corresponding to the \( \pi^n \rightarrow \pi^* \) transition. Upon irradiation with 365 nm light, a photostationary state of \( \approx 95\% \) cis-1 is acquired. Both trans-1 and cis-1 also exhibit a less intense \( n \rightarrow \pi^* \) band between 400 and 600 nm, but neither isomer absorbs at >650 nm. The absorption band of iodine, on the other hand, reaches well beyond the visible range: absorption can be observed even at >800 nm with a more concentrated sample (Figure S2). The absorption spectrum of the cis-1 + I\(_2\) mixture is the sum of the spectra of cis-1 and I\(_2\) with no indication of additional absorption bands corresponding to a charge transfer complex.

Having established that in the red/NIR region the only absorbing species is molecular iodine and the excitation should result in \( ^{3}I_2^* \) in a nondissociative manner, we proceeded to study the photoisomerization with varying iodine concentrations. This was monitored by recording the absorbance value near the maximum of the \( \pi \rightarrow \pi^* \) band of trans-1 (372 nm). Starting from trans-1, a cis-1-rich mixture was reached by illuminating the mixture with 365 nm light (Figure 2a), which is seen as a drop in the absorbance. The cis fraction in the photostationary state decreased with increasing iodine concentration due to competing absorption by the iodine molecule and subsequent iodine-catalyzed cis-to-trans isomer-

\end{figure}
the formation of a charged species during the process. PET seems probable as electron transfer processes are polarity dependent. We note that the observed solvent effect is not attributed to the solubility of oxygen, which is highest for n-hexane and lowest for dichloromethane.

Both oxidative and reductive PET processes are feasible, but for an electron-rich azobenzene such as 1, the oxidative pathway is more probable. We also screened the reaction for three other less electron rich azobenzenes: 4-methoxyazobenzene 2, unsubstituted azobenzene 3, and an azobenzene diester 4. The photocatalysis did not take place for 3 and 4 and was pronouncedly slower for 2 (Figure 4). This is another indication of an oxidative process. We also tried to test the reaction on a more electron-rich azobenzene 5 but were unable to induce the trans-to-cis photoisomerization upon excitation with 405 nm light, probably due to a ground-state interaction between 5 and iodine that blue shifts the absorption spectrum of iodine (Figure S5).

We also carried out the same experiment in nitrogen/argon-purged and freeze−pump−thaw-deaerated solutions, as both PET and TET systems are typically sensitive to oxygen. To our great surprise, photoisomerization was pronouncedly slower in the partly (see SI) deoxygenated solutions than that under ambient conditions (Figure 3, Table S1), contrary to earlier TET and PET studies. This indicates a central role for oxygen in the mechanism. As triplet iodine is capable of sensitizing singlet oxygen, which in turn has been shown to isomerize alkenes, we investigated the possibility of a singlet-oxygen-mediated route (Figure 5). Our attempts to use oxygen scavengers failed due to ground-state interaction with iodine (Figure S6), and similar results are expected with any scavenger containing nucleophilic electron pairs. Hence, we
PdPc was also found to function only in the presence of oxygen and most probably takes place between singlet oxygen and iodine-catalyzed reactions. Thus, the PET mechanism for the catalysis, as illustrated in eqs 1 and 2, the triplet excited palladium octabutoxyphthalocyanine (PdPc), an efficient singlet oxygen sensitizer with a low triplet energy (1.13 eV) and short lifetime (3.5 μs) and thus low probability of direct TET to I to occur. We first chose the concentration of PdPc (0.36 μM) so that its optical density at 770 nm was matched with that of a 200 μM iodine solution. Thus, [I O2] should be higher for the PdPc solution as it has a higher quantum yield of singlet oxygen generation. Almost no photocatalyzed isomerization was observed (Figure S7). With an equimolar (50 μM) concentration of PdPc, however, the cis-to-trans isomerization was relatively rapid, albeit slower than that for an equivalent amount of iodine (Figure S8). Most importantly, PdPc was also found to function only in the presence of oxygen (Figure S7), ruling out any direct TET or PET processes. These findings reveal that (i) singlet oxygen indeed plays a key role in the mechanism, as this is the only known product of the reaction between excited PdPc and oxygen, and (ii) iodine must have another role besides generating singlet oxygen, since the iodine-catalyzed reaction is faster than the equivalent PdPc-catalyzed reaction even though PdPc undisputedly produces more singlet oxygen to the solution. Thus, the PET most probably takes place between singlet oxygen (a strong oxidant) and I. Combining these results, we propose an oxygen-mediated PET mechanism for the catalysis, as illustrated in eqs 1-7. After the initial excitation of I2 to 1 (eq 1), the triplet excited species sensitizes the formation of singlet oxygen (O2) (eq 2), which then oxidizes I (eq 3). The formed radical cation cis-1** has an extremely low isomerization energy barrier, rapidly yielding trans-1** (eq 4). Electron transfer from O2** to trans-1** then terminates the cycle (eq 5). All of these reactions are also possible for PdPc.

\[ I_2 \rightarrow \text{\text{cis-1}'}^{+} \]  
\[ \text{\text{cis-1}'}^{+} + \text{O}_2^{2-} \rightarrow \text{trans-1}^{--} + \text{O}_2^{2-} \]  
\[ \text{trans-1}^{--} + \text{O}_2^{2-} \rightarrow \text{trans-1} + \text{3O}_2 \]  

In the case of iodine, additional steps are possible. The termination step can proceed via electron transfer from O2** to iodine (eq 6) and then to trans-1** (eq 7). In addition, it is possible that the oxygen formed when interacting with iodine is singlet excited, further accelerating the reaction. These additional routes could explain the markedly higher rate when using iodine as compared to PdPc. We also considered the possibility of iodine dissociation upon interaction with the sensitized singlet oxygen and subsequent I1 radical mechanism but ruled it out as it did not explain the solvent polarity dependence. However, we want to highlight that more mechanistic studies, both experimental and computational, should be carried out for further verification of this plausible mechanism.

\[ I_2 + O_2^{*} \rightarrow I_2^{*} + O_2 \]  
\[ \text{trans-1}^{++} + I_2^{*} \rightarrow \text{trans-1} + I_2 \]  

**CONCLUSIONS**

We have shown that singlet oxygen generated upon NIR light excitation of molecular iodine or another sensitizer can be used to induce robust azobenzene photoswitching. In fact, and most interestingly, the catalytic cycle is dependent on molecular oxygen, a feature unknown for any photocatalytic systems operating on photoswitches. Noteworthy, practically no photobleaching was observed after 1000 cycles. This is in stark contrast to our recently published TET-based NIR light catalysis, where molecular oxygen was detrimental for the performance of the azobenzene catalytic system. We envision that our concept can be further developed with other perhaps even more efficient NIR-absorbing singlet oxygen sensitizers with the same or better photoelectrochemical properties than iodine and PdPc. Moreover, our approach provides inspiration for future iodine photocatalysis also outside the field of photoswitch isomerization. Further studies should be carried out to determine what other azobenzene derivatives (and perhaps other photoswitches) the approach can be applied to. Additional experimental and computational studies are also needed to verify the mechanistic pathway of the catalysis.
